Chapter 1

Introduction

Ramsey theory is the study of structure and of disorder. The main message of Ramsey theory, which underlies all results we'll study in this course, is that *complete disorder is impossible*—any sufficiently large system, no matter how disordered, must contain within it some highly structured component. This general, highly unintuitive, philosophy manifests itself in topics as diverse as computer science, number theory, geometry, functional analysis, and, of course, graph theory, which is the topic we will mostly be focused on.

However, as Ramsey theory has connections to so many other areas of mathematics and beyond, we will also frequently pause to see how the results we have proved connect to these other fields. This is, in fact, how we begin the course, with perhaps the first-ever Ramsey-theoretic result, published by Issai Schur [47] while Frank Ramsey was only fourteen years old.

1.1 Ramsey theory before Ramsey

Like many other people, Schur was interested in Fermat's last theorem, the statement that the equation $x^q + y^q = z^q$ has no non-trivial integer solutions x, y, z for any fixed $q \geq 3$, where a solution is *trivial* if $0 \in \{x, y, z\}$ and *non-trivial* otherwise.

Proving Fermat's last theorem is (very) hard, so let's start with something simpler. There are, of course, non-trivial integer solutions to the Pythagoras equation $x^2 + y^2 = z^2$. What if we change the equation slightly, to, say, $x^2 + y^2 = 3z^2$? After playing around with it for a bit, you might be tempted to conjecture that now, there are no non-trivial integer solutions.

This conjecture is indeed true, and there is a standard technique in number theory for proving such results. Namely, if there *were* some non-trivial solution $x, y, z \in \mathbb{Z}$ to the equation $x^2 + y^2 = 3z^2$, then there would also be a non-trivial¹ solution to the same equation modulo 3, namely the equation $x^2 + y^2 \equiv 0 \pmod{3}$. However, we know that that $1^2 \equiv 2^2 \equiv 1 \pmod{3}$, and we can conclude that there *do not* exist non-trivial solutions modulo 3.

¹One has to be a bit careful here, as a non-trivial solution over \mathbb{Z} may become trivial in $\mathbb{Z}/3$. However, it is not hard to get around this issue, as one can argue that a *minimal* non-trivial solution over \mathbb{Z} cannot have all three of x, y, z divisible by 3.

A similar argument can be used to prove that many other polynomial equations have no non-trivial integer solutions, and a general phenomenon called the *Hasse principle* very roughly says that in many instances, such a technique is guaranteed to work. So it is natural to wonder whether Fermat’s last theorem can also be proved in this way. This is the question that motivated Schur², who proved that this technique *cannot* work for Fermat’s last theorem.

Theorem 1.1.1 (Schur [47]). *For any integer $q \geq 3$, there exists an integer $N = N(q)$ such that the following holds for any prime $p > N$. There exist non-zero $x, y, z \in \mathbb{Z}/p$ with*

$$x^q + y^q \equiv z^q \pmod{p}.$$

As Schur himself realized, despite proving an important and impressive result in number theory, his proof used almost no number theory! He wrote “daß [Theorem 1.1.1] sich fast unmittelbar aus einem sehr einfachen Hilfssatz ergibt, der mehr der Kombinatorik als der Zahlentheorie angehört.”³ This Hilfssatz is the following.

Theorem 1.1.2 (Schur [47]). *For any positive integer q , there exists an integer $N = N(q)$ such that the following holds. If $\llbracket N \rrbracket$ is colored in q colors, then there exist $x, y, z \in \llbracket N \rrbracket$, all receiving the same color, such that $x + y = z$.*

In this theorem, and throughout the course, we use the notation $\llbracket N \rrbracket := \{1, \dots, N\}$, and the terminology of *coloring*. By a coloring of $\llbracket N \rrbracket$ with q colors, we just mean a partition of $\llbracket N \rrbracket$ into q sets A_1, \dots, A_q , where we think of the elements of A_1 as receiving a first color, the elements of A_2 as receiving some second, distinct, color, and so on. We will also frequently use the shorthand *monochromatic* for “receiving the same color”, so the conclusion of Theorem 1.1.2 could also be stated as the existence of a monochromatic solution to $x + y = z$.

As Schur wrote, the derivation of Theorem 1.1.1 from Theorem 1.1.2 is almost immediate, but as it requires a few ideas from number theory and group theory, we will defer it for the moment. Let us first see how to prove Theorem 1.1.2. Schur proved Theorem 1.1.2 directly, but the modern, Ramsey-theoretic, perspective is to reduce Theorem 1.1.2 to an even more combinatorial lemma, which we now state.

Lemma 1.1.3. *For any positive integer q , there exists an integer $N = N(q)$ such that the following holds. If the edges of the complete graph K_N are q -colored, then there exists a monochromatic triangle.*

Proof. We will actually prove something stronger, namely an explicit upper bound on $N(q)$; we will show that $N(q) = 3q!$ satisfies the desired condition. We proceed by induction on q .

²In fact, the same question had motivated Dickson [19] a few years earlier, and he was the first to prove Theorem 1.1.1. However, his technique used very messy casework and does not at all connect to Ramsey theory, so we won’t discuss it any further.

³“that [Theorem 1.1.1] follows almost immediately from a very simple lemma, which belongs more to combinatorics than to number theory.”

The base case $q = 1$ is immediate. We are claiming that any 1-coloring of the edges of K_N , where $N = 3 \cdot 1! = 3$, contains a monochromatic triangle. But as there is only one color, and the complete graph we are “coloring” is itself a triangle, this is certainly true.

For the inductive step, suppose the result is true for $q - 1$, i.e. that any $(q - 1)$ -coloring of $E(K_{3(q-1)!})$ contains a monochromatic triangle. Fix a q -coloring of $E(K_N)$, where $N = 3q!$, and let v be any vertex of K_N . v is incident to $N - 1$ edges, each of which receives one of q colors. Therefore, by the pigeonhole principle, there is some color, say red, which appears on at least

$$\left\lceil \frac{N - 1}{q} \right\rceil = \left\lceil \frac{3q! - 1}{q} \right\rceil = \left\lceil 3(q - 1)! - \frac{1}{q} \right\rceil = 3(q - 1)!$$

edges incident to v . Let R denote the set of endpoints of these red edges, and consider the coloring restricted to R . If there is any red edge appearing in R , then it forms a red triangle together with v , and we are done. If not, then R is a set of at least $3(q - 1)!$ vertices that are colored by at most $q - 1$ colors, and we can find a monochromatic triangle in R by the inductive hypothesis. In either case we are done. \square

With Lemma 1.1.3 in hand, the proof of Theorem 1.1.2 is almost immediate. All we need to do is to translate the number-theoretic coloring into a graph-theoretic coloring.

Proof of Theorem 1.1.2. Let $N(q) = 3q!$ be chosen so that Lemma 1.1.3 holds. We are given a q -coloring χ of $\llbracket N \rrbracket$, which we convert to a q -coloring $\hat{\chi}$ of $E(K_N)$ as follows. Identify the vertices of K_N with $\llbracket N \rrbracket$, and then color an edge ab , where $1 \leq a < b \leq N$, according to the color of $b - a \in \llbracket N \rrbracket$ in χ .

As $\hat{\chi}$ is a q -coloring of $E(K_N)$, by Lemma 1.1.3, there is a monochromatic triangle in $\hat{\chi}$. Let the vertices of this triangle be a, b, c , where $a < b < c$. Let $x = b - a, y = c - b$, and $z = c - a$, and note that these satisfy $x + y = z$. Finally, note that they all receive the same color under χ , since $\chi(x) = \hat{\chi}(ab), \chi(y) = \hat{\chi}(bc)$, and $\chi(z) = \hat{\chi}(ac)$, and we assumed that a, b, c is a monochromatic triangle under $\hat{\chi}$. \square

This completes the combinatorial part of Schur’s work. For completeness, let’s see how to derive Theorem 1.1.1 from Theorem 1.1.2. As this topic is somewhat outside the main narrative of the class, it will not be covered in lecture; throughout the notes we use a gray box, as follows, to indicate material that was skipped.

Deduction of Theorem 1.1.1 from Theorem 1.1.2

Proof of Theorem 1.1.1. Let $N = N(q)$ be as in Theorem 1.1.2, and fix a prime $p > N$. We recall the well-known fact that the set $\Gamma := \{x^q : 0 \neq x \in \mathbb{Z}/p\}$ forms a subgroup of the multiplicative group $(\mathbb{Z}/p)^\times$, and the index of this subgroup is at most[†] q . Therefore, there are at most q cosets of Γ which partition the non-zero elements of \mathbb{Z}/p . By identifying the non-zero elements of \mathbb{Z}/p with $\llbracket p - 1 \rrbracket \supseteq \llbracket N \rrbracket$, we obtain a q -coloring of $\llbracket N \rrbracket$ according to these cosets.

Now, by Theorem 1.1.2, there must exist monochromatic $a, b, c \in \llbracket N \rrbracket$ such that $a + b = c$. As these three numbers receive the same color, they must lie in some single coset $\alpha\Gamma$ of Γ , for

some $\alpha \in (\mathbb{Z}/p)^\times$. By the definition of Γ , this means that we can write

$$a \equiv \alpha x^q \pmod{p}, \quad b \equiv \alpha y^q \pmod{p}, \quad c \equiv \alpha z^q \pmod{p},$$

for some non-zero $x, y, z \in \mathbb{Z}/p$. The equation $a + b = c$ remains true when we reduce it mod p , so we conclude that

$$\alpha x^q + \alpha y^q \equiv \alpha z^q \pmod{p}.$$

As α is invertible in \mathbb{Z}/p , and as $x, y, z \neq 0$, we obtained the desired non-trivial solution $x^q + y^q \equiv z^q \pmod{p}$. \square

[†]More precisely, the index is exactly $\gcd(q, p-1)$.

Chapter 2

Classical Ramsey numbers

2.1 Ramsey's theorem and upper bounds on Ramsey numbers

While Schur's theorem can be seen as an early example of Ramsey theory, the theory did not really get going until Frank Ramsey's pioneering work [42] in 1929. Ramsey's theorem, as it is now called, is a generalization of Lemma 1.1.3 from triangles to arbitrary cliques.

Theorem 2.1.1 (Ramsey [42]). *For all positive integers k, q , there exists an integer $N = N(k, q)$ such that the following holds. If the edges of the complete graph K_N are q -colored, then there exists a monochromatic K_k , that is, k vertices such that all the $\binom{k}{2}$ edges between them receive the same color.*

Given this theorem, which we will shortly prove, we can make a definition that will be central for much of the rest of the course.

Definition 2.1.2. Given positive integers k, q , the q -color Ramsey number of K_k , denoted $r(k; q)$, is the least N such that the conclusion of Theorem 2.1.1 is true. That is, $r(k; q)$ is the minimum integer N such that every q -coloring of $E(K_N)$ contains a monochromatic K_k .

In case $q = 2$, we usually abbreviate $r(k; 2)$ as simply $r(k)$, and usually refer to the 2-color Ramsey number as simply the *Ramsey number*.

In this language, Theorem 2.1.1 can equivalently be stated as saying that $r(k; q) < \infty$ for all k, q . In fact, for much of this course, we will be interested not just in the fact that such Ramsey numbers are finite, but in quantitative estimates on how large they are.

For now, let's focus on the case $q = 2$. Ramsey's original proof of Theorem 2.1.1 showed that $r(k) \leq k!$ for all k . But a few years later, a different proof was found by Erdős and Szekeres [24], in another foundational paper of the field. In order to present their proof, we need to define a slightly more general notion of Ramsey number.

Definition 2.1.3. Given positive integers k, ℓ , we denote by $r(k, \ell)$ the *off-diagonal Ramsey number*, defined to be the least N such that every 2-coloring of $E(K_N)$ with colors red and blue contains a red K_k or a blue K_ℓ .

Note that $r(k, \ell) = r(\ell, k)$ as the colors play symmetric roles, and that $r(k) = r(k, k)$.

Theorem 2.1.4 (Erdős–Szekeres). *For all positive integers k, ℓ , we have*

$$r(k, \ell) \leq \binom{k + \ell - 2}{k - 1}.$$

In particular, we have

$$r(k) \leq \binom{2k - 2}{k - 1} < 4^k.$$

Proof. We proceed by induction on $k + \ell$, with the base case¹ $k = \ell = 1$ being trivial. For the inductive step, the key claim is that the following inequality holds:

$$r(k, \ell) \leq r(k - 1, \ell) + r(k, \ell - 1). \quad (2.1)$$

To prove (2.1), fix a red/blue coloring of $E(K_N)$, where $N = r(k - 1, \ell) + r(k, \ell - 1)$, and fix some vertex $v \in V(K_N)$. Suppose for the moment that v is incident to at least $r(k - 1, \ell)$ red edges, and let R denote the set of endpoints of these red edges. By definition, as $|R| \geq r(k - 1, \ell)$, we know that R contains a red K_{k-1} or a blue K_ℓ . In the latter case we have found a blue K_ℓ (so we are done), and in the former case we can add v to this red K_{k-1} to obtain a red K_k (and we are again done).

So we may assume that v is incident to fewer than $r(k - 1, \ell)$ red edges. By the exact same argument, just interchanging the roles of the colors, we may assume that v is incident to fewer than $r(k, \ell - 1)$ blue edges. But then the total number of edges incident to v is at most

$$(r(k - 1, \ell) - 1) + (r(k, \ell - 1) - 1) = N - 2,$$

which is impossible, as v is adjacent to all $N - 1$ other vertices. This is a contradiction, proving (2.1).

We can now complete the induction. By (2.1) and the inductive hypothesis, we find that

$$r(k, \ell) \leq r(k - 1, \ell) + r(k, \ell - 1) \leq \binom{(k - 1) + \ell - 2}{(k - 1) - 1} + \binom{k + (\ell - 1) - 2}{k - 1} = \binom{k + \ell - 2}{k - 1},$$

where the final equality is Pascal's identity for binomial coefficients. \square

A similar argument works when the number of colors is more than 2. If we denote by $r(k_1, \dots, k_q)$ the *off-diagonal multicolor Ramsey number* (defined in the natural way), we obtain the following generalization of Theorem 2.1.4, which you will prove on the homework.

Theorem 2.1.5. *For all positive integers q and k_1, \dots, k_q , we have*

$$r(k_1, \dots, k_q) \leq \binom{k_1 + \dots + k_q - q}{k_1 - 1, \dots, k_q - 1},$$

where the right-hand side denotes the multinomial coefficient. In particular,

$$r(k; q) < q^{qk}.$$

¹If you don't like starting the induction with $k = \ell = 1$ —what does a monochromatic K_1 mean, exactly?—you should convince yourself that the base case $k = \ell = 2$ also works.

2.2 Lower bounds on Ramsey numbers

The Erdős–Szekeres bound, Theorem 2.1.4, gives us the upper bound $r(k) < 4^k$, which improves on Ramsey’s earlier bound of $r(k) \leq k!$. To understand how good this bound is, we would like to obtain some *lower bounds* on $r(k)$.

Thinking about the definition of Ramsey numbers, we see that proving a lower bound of $r(k) > N$ boils down to exhibiting a 2-coloring of $E(K_N)$ with no monochromatic K_k . Perhaps the simplest such coloring is the *Turán coloring*, which proves the following result (and which we will meet again later in the course).

Proposition 2.2.1. *For any positive integer k , we have $r(k) > (k - 1)^2$.*

Proof. Let $N = (k - 1)^2$. We split the vertex set of K_N into $k - 1$ parts, each of size $k - 1$. We color all edges within a part red, and all edges between parts blue. The red graph is a disjoint union of $k - 1$ copies of K_{k-1} , so there is certainly no red K_k . On the other hand, as there are only $k - 1$ parts, the pigeonhole principle implies that any set of k vertices must include two vertices in one part; these two vertices span a red edge, and thus there is no blue K_k either. \square

Is Proposition 2.2.1 tight? It’s not too hard to see that the answer is no. Indeed, already for $k = 2$, Proposition 2.2.1 implies that $r(2) > 4$, and it is not hard to show that in fact $r(2) = 5$, as witnessed by the following coloring.

Nonetheless, it is not clear how to do much better than Proposition 2.2.1 in general. Indeed, I’ve heard that in the 1940s, Turán believed that the Erdős–Szekeres bound is way off, and that the truth is $r(k) = \Theta(k^2)$ (i.e. that Proposition 2.2.1 is best possible up to a constant factor). As it turns out, this belief was *way* off.

Theorem 2.2.2 (Erdős [23]). *For any $k \geq 2$, we have $r(k) \geq 2^{k/2}$.*

Together with Theorem 2.1.4, this proves that $r(k)$ really does grow as an exponential function of k , although these theorems do not tell us the precise growth rate. Theorem 2.2.2 was a major breakthrough not only—or even primarily—because of the result itself. In proving Theorem 2.2.2, Erdős introduced the so-called *probabilistic method* to combinatorics. This method would quickly become one of the most important tools in combinatorics, and will recur frequently throughout this course.

Proof of Theorem 2.2.2. Fix k , and let² $N = 2^{k/2}$. The claimed bound is trivial for $k = 2$, so let's assume $k \geq 3$. Consider a *random* 2-coloring of $E(K_N)$. Namely, for each edge of K_N , we assign it color red or blue with probability $\frac{1}{2}$, making these choices independently over all edges. We begin by estimating the probability that this coloring contains a monochromatic K_k .

For any fixed set of k vertices, the probability that it forms a monochromatic K_k is precisely $2^{1-\binom{k}{2}}$. This is because we have $\binom{k}{2}$ coin tosses, which we need to all agree, and we have two options for the shared outcome (hence the extra +1 in the exponent). Moreover, there are exactly $\binom{N}{k}$ possible k -sets we need to consider. Therefore,

$$\Pr(\text{there is a monochromatic } K_k) \leq \binom{N}{k} 2^{1-\binom{k}{2}},$$

where we have applied the *union bound* $\binom{N}{k}$ times; this is the bound that says that the probability that A *or* B happens is at most the sum of the probability that A happens and the probability that B happens.

Note that $\binom{N}{k} < N^k/k!$ and that $k! > 2^{1+k/2}$ for all $k \geq 3$. Therefore, we have

$$\binom{N}{k} 2^{1-\binom{k}{2}} < \frac{N^k}{k!} \cdot 2^{1-\frac{k^2-k}{2}} < \frac{N^k}{2^{1+\frac{k}{2}}} \cdot 2^{1+\frac{k}{2}-\frac{k^2}{2}} = \left(N \cdot 2^{-\frac{k}{2}}\right)^k = 1, \quad (2.2)$$

where the final equality is our choice of N .

Putting this all together, we find that in this random coloring, the probability that there is a monochromatic K_k is *strictly less than one*. Therefore, there must exist *some* coloring of $E(K_N)$ with no monochromatic K_k , as if such a coloring did not exist, the probability above would be exactly one. This completes the proof. \square

It's worth stressing the miraculous magic trick that takes place in the proof of Theorem 2.2.2. Unlike in Proposition 2.2.1, Erdős does not give any sort of explicit description of a coloring on $2^{k/2}$ vertices with no monochromatic K_k . Instead, he argues that such a coloring must exist for probabilistic reasons, but this argument gives absolutely no indication of what such a coloring looks like. In fact, the following remains a major open problem.

Open problem 2.2.3 (Erdős). *For some $\varepsilon > 0$ and all sufficiently large k , explicitly construct a 2-coloring on $(1 + \varepsilon)^k$ vertices with no monochromatic K_k .*

There was a great deal of partial progress over the years, much of it exploiting a deep and surprising connection to the topic of *randomness extraction* in theoretical computer science. Just last year, there was a major breakthrough on this problem.

²The astute reader will notice that $2^{k/2}$ is not an integer unless k is even. Thus, we should really write here $N = \lceil 2^{k/2} \rceil$. However, once the computations we do become more complicated, keeping track of such floor and ceiling signs becomes not just annoying, but actively confusing. Therefore, for the rest of the course, we'll omit floor and ceiling signs unless they are actually crucial, and it will be understood that any quantity that should be an integer but doesn't look like one should be rounded up or down to an integer.

Theorem 2.2.4 (Li [38]). *For some absolute constant $\varepsilon > 0$ and all sufficiently large k , there is an explicit 2-coloring on 2^{k^ε} vertices with no monochromatic K_k .*

By using a random q -coloring, one can adapt the proof of Theorem 2.2.2 and prove that for any $k, q \geq 3$, we have

$$r(k; q) > q^{k/2}.$$

Together with Theorem 2.1.5, this shows that for any fixed $r(k; q)$ grows exponentially as a function of k for any fixed q . However, for fixed k , the upper and lower bounds are rather far apart—the lower bound is merely polynomial in q , whereas the upper bound is super-exponential in q . For several decades this was the state of the art, until Abbott³ [1] noticed a simple trick that does much better.

Proposition 2.2.5 (Abbott [1]). *For all positive integers k, q_1, q_2 , we have*

$$r(k; q_1 + q_2) - 1 \geq (r(k; q_1) - 1)(r(k; q_2) - 1). \quad (2.3)$$

As a consequence, we have

$$r(k; q) > 2^{\lfloor \frac{k}{2} \rfloor \lfloor \frac{q}{2} \rfloor}.$$

Proof. Let $N_1 = r(k; q_1) - 1$ and $N_2 = r(k; q_2) - 1$. By assumption, we have colorings $\chi_i : V(K_{N_i}) \rightarrow [q_i]$, for $i = 1, 2$, both of which avoid monochromatic K_k . Let $N = N_1 N_2$, and identify the vertex set of K_N with $V(K_{N_1}) \times V(K_{N_2})$. We can now define a coloring $\chi : E(K_N) \rightarrow [q_1 + q_2]$ as follows. It is easiest to understand with the following picture, which shows how to convert two 2-colorings of $E(K_5)$ into a 4-coloring of $E(K_{25})$, maintaining the property of having no monochromatic triangle.

Formally, given a pair of vertices $(a_1, b_1), (a_2, b_2) \in V(K_{N_1}) \times V(K_{N_2}) \cong V(K_N)$, we define

$$\chi((a_1, b_1), (a_2, b_2)) = \begin{cases} \chi_1(a_1, a_2) & \text{if } a_1 \neq a_2, \\ q_1 + \chi_2(b_1, b_2) & \text{otherwise.} \end{cases}$$

This is a $(q_1 + q_2)$ -coloring of $E(K_N)$, and one can readily verify that there is no monochromatic K_k , as such a monochromatic clique could be used to obtain a monochromatic K_k in either χ_1 or χ_2 . Thus proves the claimed inequality (2.3).

To use it, we recall that we proved in Theorem 2.2.2 that $r(k; 2) \geq 2^{k/2} + 1$. Applying (2.3) $\lfloor q/2 \rfloor$ times, we conclude that $r(k; q) > (2^{k/2})^{\lfloor q/2 \rfloor}$, as claimed. \square

³An earlier version of these notes, as well as many papers on the topic, attribute this result to Lefmann [37], and note that the trick goes back at least to work of Chung [11]. But the paper of Abbott is even earlier.

2.3 The past and the future

Let us now zoom out a bit and discuss both some history, and a preview of what is to come in (part of) the rest of the course. Until five years ago, the results stated above were essentially the state of the art. In the case of two colors, we knew

$$2^{\frac{k}{2}} < r(k) < 4^k,$$

and more generally for q colors we had (say for simplicity that q is even)

$$2^{\frac{qk}{4}} < r(k; q) < q^{qk}.$$

There were a number of important papers that obtained slight improvements on some of these bounds [13, 44, 49], but no one knew how to improve any of the exponential constants appearing above. But in recent years there have been a number of important breakthroughs on the problems discussed above.

The first concerns the lower bound on $r(k; q)$ when $q \geq 3$ is fixed. Here, there was a major breakthrough of Conlon and Ferber in 2020 [16], followed shortly thereafter by improvements of myself [53] and Sawin [46]. The current state of the art, due to Sawin, is the following result.

Theorem 2.3.1 (Sawin [46]). *For fixed $q \geq 3$, we have*

$$r(k; q) > \left(2^{0.383796q - 0.267592}\right)^{k - o(k)},$$

where the $o(k)$ term grows asymptotically slower than k as $k \rightarrow \infty$.

This is better than what is given by Proposition 2.2.5, because $0.384 > \frac{1}{4}$. The proof is ingenious but quite simple, and we will see it later in the course. We remark that while these recent breakthroughs have improved the lower bound given in Proposition 2.2.5, they have so far been unable to answer the main question about multicolor Ramsey numbers, which Erdős offered \$100 for.

Open problem 2.3.2 (Erdős, \$100). *For fixed $k \geq 3$, does $r(k; q)$ grow exponentially or super-exponentially as a function of q ?*

The next breakthrough, chronologically, came in March 2023, when Campos, Griffiths, Morris, and Sahasrabudhe [9] obtained the first improvement to the exponential constant in Theorem 2.1.4.

Theorem 2.3.3 (Campos–Griffiths–Morris–Sahasrabudhe [9]). *$r(k) < 3.9999^k$ for all sufficiently large k .*

This might seem like a small improvement, but this was a really major breakthrough, since this problem had been intractably stuck for almost 90 years. The proof of Theorem 2.3.3

is completely elementary, but rather involved; we will hopefully see a sketch of the argument later in the course, time permitting.

The final breakthrough that I want to talk about came out just three months later, in June 2023, and was a result of Mattheus and Verstraëte [39] about off-diagonal Ramsey numbers. Before stating their result, let's back up and learn a bit about off-diagonal Ramsey numbers, which we have not yet seriously discussed.

Generally speaking, when we talk about off-diagonal Ramsey numbers, we are interested in the function $r(s, k)$ (as in Definition 2.1.3), where we think of s as fixed and $k \rightarrow \infty$. If we specialize Theorem 2.1.4 to this setting, we find that for any fixed $s \geq 2$, we have

$$r(s, k) \leq \binom{k + (s-2)}{s-1} = O_s(k^{s-1}).$$

Here, and throughout the course, we use the big- O notation $f = O(g)$ to mean that $f(x) \leq C \cdot g(x)$ for an absolute constant $C > 0$. In case we use a subscript, as the subscript s above, this means that the constant C may depend on the parameter s , i.e. that this bound should be thought of for fixed s . It is easy to see that $r(2, k) = k$ for all k , hence this bound is tight for $s = 2$. For all larger s , a polylogarithmic improvement to the upper bound was obtained by Ajtai, Komlós, and Szemerédi [2], who proved that for fixed $s \geq 3$, we have

$$r(s, k) = O_s \left(\frac{k^{s-1}}{(\log k)^{s-2}} \right).$$

We will see a proof of this result later in the course. In particular, in the case $s = 3$, their result says that

$$r(3, k) = O \left(\frac{k^2}{\log k} \right).$$

Even before the Ajtai–Komlós–Szemerédi theorem was proved, Erdős [20] used a very sophisticated and intricate probabilistic argument to obtain a nearly matching lower bound,

$$r(3, k) = \Omega \left(\frac{k^2}{(\log k)^2} \right),$$

where the big- Ω notation $f = \Omega(g)$ is equivalent to $g = O(f)$. Erdős's result was re-proved by Spencer [50] using a different (and simpler) probabilistic technique, but the logarithmic gap remained for a long time until Kim [33] finally managed to prove that the upper bound is correct, that is

$$r(3, k) = \Theta \left(\frac{k^2}{\log k} \right),$$

where the big- Θ notation $f = \Theta(g)$ means that $f = O(g)$ and $f = \Omega(g)$. More recent improvements to the lower and upper bounds [7, 25, 48] have been able to almost completely determine the asymptotics of $r(3, k)$; we now know that

$$\left(\frac{1}{4} - o(1) \right) \frac{k^2}{\ln k} \leq r(3, k) \leq (1 + o(1)) \frac{k^2}{\ln k},$$

where \ln denotes the natural logarithm, and where the little- o notation $f = o(g)$ means that $\lim_{x \rightarrow \infty} f(x)/g(x) = 0$.

Despite this string of successes, very little remains known about the asymptotics of $r(s, k)$ for fixed $s \geq 4$. The best known lower bound, again due to Spencer [50] (with polylogarithmic improvements due to Bohman–Keevash [6]) is of the form $r(s, k) \geq k^{\frac{1}{2}(s+1)+o(1)}$, compared to the upper bound of $r(s, k) \leq k^{s-1-o(1)}$. In particular, for $s = 4$, there is a gap of $1/2$ in the exponent. Or at least, there *was*, until the Mattheus–Verstraëte breakthrough [39].

Theorem 2.3.4 (Mattheus–Verstraëte [39]). *We have*

$$r(4, k) = \Omega\left(\frac{k^3}{(\log k)^4}\right).$$

This matches the Ajtai–Komlós–Szemerédi upper bound up to a factor of $\Theta((\log k)^2)$. Their proof builds on a long line of recent work [3, 14, 40], and happens to be closely related to the techniques used to prove Theorem 2.3.1 (the improved lower bound for $r(k; q)$). As such, we will see the proof of Theorem 2.3.4 later in the course.

Chapter 3

Lower bounds on multicolor Ramsey numbers

Recall that Abbott [1] proved that $r(k; q) > 2^{\lfloor \frac{k}{2} \rfloor \lfloor \frac{q}{2} \rfloor}$; for even q we can write this as $r(k; q) > (2^{q/4})^k$. We will now see how to improve this bound for all $q \geq 3$. In so doing, we will also lay the groundwork for proving lower bounds on the off-diagonal Ramsey numbers $r(3, k)$ and $r(4, k)$. The ideas in this section go back at least to work of Alon–Rödl [3], and were crystallized in a series of works [16, 31, 40, 46, 53].

3.1 Random sampling and random homomorphisms

Let's suppose we wish to prove a lower bound on the two-color Ramsey number $r(s, k)$. If we can find a graph G that has no clique of order s and no independent set of order k , then we've found such a lower bound: $r(s, k)$ is greater than the number of vertices of G , since we can color the edges of G red and the non-edges blue. But since finding such graphs is hard, it would be nice to be able to lower-bound $r(s, k)$ by finding a graph G with some weaker property.

It turns out that this is possible. Suppose we now have a graph G with no K_s , but let's not assume that it has no independent sets of order k . Instead, let's suppose that G has “few” independent sets of order k . Concretely, assume that G has at most M^k independent sets of order k , for some parameter M (note that it is natural to parametrize things in this way, since there are exponentially many k -sets of vertices in G). It turns out that as long as M is not too big, we can use this G to get a good lower bound on $r(s, k)$, by *random sampling*.

Lemma 3.1.1 (Random sampling). *Let G be a K_s -free graph on N vertices, and suppose that G has at most M^k independent sets of order k . Then*

$$r(s, k) \geq \frac{N}{4M}.$$

Proof. We will randomly sample a subgraph H of G , by keeping each vertex of G independently with probability p , to be chosen later. Since G is K_s -free, its subgraph H is

K_s -free as well. Additionally, each independent set of order k in G will survive in H with probability p^k . So the expected number of independent sets of order k in H is at most $p^k M^k = (pM)^k$. By choosing $p = 1/(2M)$, this number is less than $1/2$, so the probability that H has no independent set of order k is at least $1/2$. Additionally, with high probability, H has at least $pN/2$ vertices, by standard probabilistic tail bounds¹. So we find that with positive probability, H is a graph on at least $N/(4M)$ vertices with no K_s or $\overline{K_k}$, proving that $r(s, k) \geq N/(4M)$, as claimed. \square

In order to extend these ideas further, it will be convenient to take a different perspective on Lemma 3.1.1. Specifically, rather than keeping each vertex of G with probability p , we will pick a random function from a set of pN vertices to $V(G)$, and “pull back” the graph structure. Of course, if $p \ll 1$, then this random function will have no collisions with high probability, and so we will exactly get the random induced subgraph we got before, except that we’ll have exactly pN vertices (rather than a binomial distribution on the number of vertices), but this difference is immaterial. The reason for taking this change of perspective is that it is much more amenable to using more than two colors: we can just pick more random functions and overlay them, as we’ll soon see.

Concretely, suppose that G is a K_s -free graph on N vertices with at most M^k independent sets of order at most² k . Let $n = pN$ for some parameter p , and pick a uniformly random function $f : [n] \rightarrow V(G)$. Define a graph H on vertex set $[n]$ by setting $\{u, v\} \in E(H)$ if $\{f(u), f(v)\} \in E(G)$; note that in particular we only connect u and v if $f(u) \neq f(v)$, which implies that H is also K_s -free. Then for any given set $K \subset [n]$ of order $|K| = k$, and any fixed $U \subseteq V(G)$ of order $|U| \leq k$, the probability that $f(K) \subseteq U$ is at most $(k/N)^k$. Thus, the probability that K is independent in H is at most $(kM/N)^k$, as there are at most M^k choices for such a U that is independent in G . As there are $\binom{n}{k}$ choices for this K , we see by the union bound that

$$\Pr(H \text{ has an independent set of order } k) \leq \binom{n}{k} \left(\frac{kM}{N} \right)^k \leq \left(\frac{epN}{k} \frac{kM}{N} \right)^k = (epM)^k,$$

and we can recover the result of Lemma 3.1.1—up to the constant factor—by setting $p = 1/(2eM)$.

However, as indicated above, the power of this perspective is that it easily extends to more colors. Indeed, suppose that we instead pick independent uniformly random functions $f_1, \dots, f_r : [n] \rightarrow V(G)$. We color the edges of K_n in $r + 1$ colors, as follows. If there is some $i \in [r]$ such that $\{f_i(u), f_i(v)\} \in E(G)$, then we color $\{u, v\}$ by the minimum such i . If

¹As I am not assuming any probabilistic background in this course, I won’t get into exactly what this means, but if you’re curious you should look up Chebyshev’s inequality or the Chernoff bound, and verify that either of them will suffice to prove this statement. Strictly speaking, to make this argument work, we’d have to assume that $N > 10M$ (or some other similar bound). But given that the lemma statement is uninteresting if M and N have the same order, let’s not worry about this technicality.

²Note that we’ve slightly strengthened this assumption, bounding the number of independent sets of order *at most* k . As it turns out, this is usually OK: many techniques that bound the number of independent sets of order exactly k will also work here.

not, we color $\{u, v\}$ by color $r + 1$. Then each of the first r colors is K_s -free, by the above. Additionally, the probability that some fixed k -set K is monochromatic in the last color is at most $(kM/N)^{r^k}$, since we have a probability $(kM/N)^k$ for each function f_i , and these probabilities are independent. Therefore, by the union bound, we find that the probability that the last color has a clique of order k is at most

$$\binom{n}{k} \left(\frac{kM}{N} \right)^{r^k} \leq \left(\frac{pk^r M^r}{N^{r-1}} \right)^k. \quad (3.1)$$

We conclude the following generalization of Lemma 3.1.1.

Lemma 3.1.2 (Random homomorphisms). *Let G be a K_s -free graph on N vertices, and suppose that G has at most M^k independent sets of order at most k . Then*

$$r(\underbrace{s, \dots, s}_{r \text{ times}}, k) \geq \frac{N^r}{2k^r M^r}.$$

Proof. We set $p = N^{r-1}/(2k^r M^r)$, so that the quantity in (3.1) is less than 1. Then we see that the coloring described above has no K_s in the first r colors, and no K_k in the final color, and has $n = pN$ vertices. \square

Of course, even this isn't the most general form of this lemma that we could prove, since there's no real reason to have f_1, \dots, f_r all have the same codomain. Indeed, in [31], this idea was used to obtain lower bounds on many off-diagonal multicolor Ramsey numbers.

The crucial thing to observe about Lemma 3.1.2 is that p is not a probability, and in particular, it does not need to be less than 1! If $p > 1$, then $n = pN$ will be larger than N , and the functions f_1, \dots, f_r will no longer be making random subgraphs of G . Instead, they will be forming random *blowups* of G , and thus the coloring we use in Lemma 3.1.2 is obtained by randomly overlaying r random blowups of G , and then coloring all uncolored edges with the final color. This idea of overlaying random blowups to obtain lower bounds on multicolor Ramsey numbers goes back to Alon and Rödl [3], though they didn't use the perspective of random homomorphisms. The observation that the Alon–Rödl approach and the Mubayi–Verstraëte approach are both instances of the same general technique is due to Xiaoyu He, and our paper [31] uses this observation to combine the Alon–Rödl and Mubayi–Verstraëte approaches and obtain unified bounds on multicolor Ramsey numbers. In my opinion, the fact that random induced subgraphs and random blowups are “the same thing” is a very powerful observation, and it's the main message I'd like to get across in this section.

3.2 The Conlon–Ferber argument

In Lemma 3.1.2, we gave all remaining edges the same color, and then used a simple union bound to estimate the probability of a monochromatic K_k . The Conlon–Ferber idea is to actually use two colors for these remaining edges, choosing randomly for each edge. Since we

know that random colorings generally have small monochromatic cliques, it stands to reason that doing this will improve the lower bound on the Ramsey number. Of course, doing this is costly, in the sense that we have to add a new color, so we are obtaining a strengthened bound on a different Ramsey number. The precise statement, implicit in [16, 53] and explicit in [46], is as follows.

Lemma 3.2.1. *Let G be a K_s -free graph on N vertices, and suppose that G has at most M^k independent sets of order at most k . Then*

$$r(\underbrace{s, \dots, s}_{r \text{ times}}, k, k) \geq \frac{2^{k/2} N^r}{4k^r M^r}.$$

Proof. As indicated above, we pick a parameter p , set $n = pN$, and choose r random functions $f_1, \dots, f_r : \llbracket n \rrbracket \rightarrow V(G)$. We color $E(K_n)$ by assigning the first r colors as before, with $\{u, v\}$ getting color i only if $\{f_i(u), f_i(v)\} \in E(G)$. For the uncolored edges, we assign one of the colors $r+1, r+2$ uniformly at random, independently for each uncolored edge. Then as above, we know that the first r colors are K_s -free. For the final two colors, let's estimate the probability that a k -set $K \subset \llbracket n \rrbracket$ is monochromatic. For K to be monochromatic, it must first not contain any edges of the first r colors, which we know happens with probability at most $(kM/N)^{rk}$. Then, there is a probability $2^{1-\binom{k}{2}}$ that all the pairs of K get assigned the same color among $\{r+1, r+2\}$. Putting this all together with the union bound, we see that the probability that K_n has a monochromatic K_k in one of the last two colors is at most

$$\binom{n}{k} 2^{1-\binom{k}{2}} \left(\frac{kM}{N} \right)^{rk} \leq \left(pN \cdot 2^{1-\frac{k}{2}} \cdot \frac{k^r M^r}{N^r} \right)^k = \left(p \frac{2k^r M^r}{2^{k/2} N^{r-1}} \right)^k.$$

So if we take $p = 2^{k/2} N^{r-1} / (4k^r M^r)$, this probability will be less than 1, and we'll obtain a coloring with no K_s in the first r colors and no K_k in the final two colors. This gives that

$$r(\underbrace{s, \dots, s}_{r \text{ times}}, k, k) \geq n = pN = \frac{2^{k/2} N^r}{4k^r M^r}. \quad \square$$

3.3 Actually getting a lower bound on $r(k; q)$

So far, all of the results proved above are of the form “if a graph G with certain properties exists, then we obtain a lower bound on some Ramsey number”. But we haven't yet proved that any such graph G exists!

In many settings, such as the lower bounds on $r(3, k)$ and $r(4, k)$ that we will discuss shortly, finding such graphs is quite difficult, and is basically the crux of the argument (see also [3, 40]). In their work improving the lower bound on $r(k; q)$, Conlon and Ferber [16] used an ingenious linear-algebraic construction of a graph with such properties, and you will have the opportunity to explore this graph in the homework. However, as observed by Sawin [46], it is more efficient to use a *random* graph.

Lemma 3.3.1. *For every $k \geq 10$, there exists a K_k -free graph G on $N = 2^{k/2}$ vertices with at most M^k independent sets of order at most k , where $M = 2 \cdot 2^{k/8}$.*

Proof. We consider a uniformly random graph G on N vertices, i.e. where each pair is included as an edge of G with probability $\frac{1}{2}$, independently over all choices. By the same computation as in Theorem 2.2.2, we see that G is K_k -free with probability at least $\frac{2}{3}$. Any set of order m is an independent set in G with probability $2^{-\binom{m}{2}}$, hence the expected number of independent sets of order at most k in G is

$$\sum_{m=1}^k \binom{N}{m} 2^{-\binom{m}{2}} \leq N + \binom{N}{2} + \sum_{m=3}^k \binom{N}{m} 2^{-\binom{m}{2}} \leq N^2 + \sum_{m=3}^k (N \cdot 2^{-\frac{m}{2}})^m,$$

where the final step is the same computation as in equation (2.2). Recalling that we chose $N = 2^{k/2}$, we can write

$$(N \cdot 2^{-\frac{m}{2}})^m = \left(2^{\frac{k-m}{2}}\right)^m = \left(2^{\frac{k-m}{2} \cdot \frac{m}{k}}\right)^k.$$

The function $(k-m)m/(2k)$ is a quadratic function of m , and it is easy to see that it is maximized at $m = k/2$, where it takes on the value $k/8$. Therefore, the expected number of independent set of order at most k in G is upper-bounded by

$$N^2 + (k-2) \cdot \left(2^{\frac{k}{8}}\right)^k \leq \frac{1}{3} \left(2 \cdot 2^{\frac{k}{8}}\right)^k = \frac{1}{3} M^k,$$

where the inequality holds by our assumption that $k \geq 10$.

Now, an application of Markov's inequality shows that with probability at least $\frac{2}{3}$, G has at most M^k independent sets of order at most k . As we also said that G is K_k -free with probability at least $\frac{2}{3}$, we conclude that there exists a graph G with the claimed properties. \square

Plugging this result into Lemma 3.2.1 (with $s = k$ and $r = q - 2$), we obtain

$$r(k; q) \geq \frac{2^{k/2} N^{q-2}}{4k^{q-2} M^{q-2}} = \frac{(2^{(q-1)/2})^k}{4(2k)^{q-2} (2^{(q-2)/8})^k} = \left(2^{\frac{q-1}{2} - \frac{q-2}{8}}\right)^{k-o(k)} = \left(2^{\frac{3}{4}q - \frac{1}{4}}\right)^{k-o(k)}, \quad (3.2)$$

where in the second equality we use the fact that $4(2k)^{q-2}$ is a polynomial in k , and thus is of the form $2^{o(k)}$ as $k \rightarrow \infty$ (with q fixed). Note that this bound is already better than that given by Proposition 2.2.5 for any $q \geq 3$, whereas (3.2) matches Proposition 2.2.5 (and Theorem 2.2.2) for $q = 2$. This should not be surprising, since for $q = 2$ we use $r = q - 2 = 0$ random homomorphisms, and thus this construction is simply the same as in Theorem 2.2.2!

The bound (3.2) was proved in [53], by using the linear-algebraic graph of Conlon–Ferber rather than the random graph G constructed in Lemma 3.3.1 (both constructions end up having the same value of N/M , and thus yield the same bound). One of Sawin's main observations in [46] is that by running the same argument with a random graph of edge density p slightly less than $1/2$, one can get the better exponent in Theorem 2.3.1.

Lemma 3.3.2 (Sawin [46]). *For any $k \geq 4$ and $p \in (0, 1)$, there exists a K_k -free graph G on $N = p^{-k/2}$ vertices with at most M^k independent sets of order at most k , where*

$$M = N \cdot 2^{k \cdot \frac{(4 \log(1-p) - \log(p)) \log(p)}{8 \log(1-p)} - o(k)},$$

and the logarithms are to base 2.

The proof of this lemma is the same as that of Lemma 3.3.1, except that now when defining the random graph G , we include every pair as an edge with probability p . As our goal is to pick M as small as possible, to obtain as strong a lower bound from Lemma 3.2.1 as possible, we wish to minimize the exponent as a function of p ; one can check that this minimum is attained at $p \approx 0.455$, and plugging this into Lemma 3.2.1 yields the bound in Theorem 2.3.1.

Chapter 4

Off-diagonal Ramsey numbers

Let us now turn our attention to the off-diagonal Ramsey number $r(3, k)$. Already in Lemma 3.1.1, we saw the basic tool that we will use to obtain lower bounds on this function (the idea of applying Lemma 3.1.1 to this problem is due to Mubayi–Verstraëte [40]). However, before we get there, let us discuss upper bounds.

4.1 Upper bounds on off-diagonal Ramsey numbers

Recall that as a consequence of the general Erdős–Szekeres bound, Theorem 2.1.4, we have

$$r(3, k) \leq \binom{k+1}{2} \leq k^2. \quad (4.1)$$

In this section, we will prove a better upper bound, of the form $r(3, k) = O(k^2/\log k)$, originally due to Ajtai–Komlós–Szemerédi [2] (improving on earlier work of Graver–Yackel [28]), although we will follow a somewhat more streamlined proof due to Shearer [48]. Before we do that, let’s spend a moment thinking about the bound $r(3, k) \leq k^2$. Setting $n = k^2$, this bound can equivalently be phrased as follows: any n -vertex triangle-free graph G contains an independent set of order \sqrt{n} . In this language, this is rather easy to prove, as follows. If G has a vertex v of degree at least \sqrt{n} , then the triangle-free condition implies that the neighborhood of v is an independent set of order at least \sqrt{n} . On the other hand, if all vertices of G have degree strictly less than \sqrt{n} , we can greedily build up an independent set A as follows. We pick a vertex v_1 , place v_1 into A , and then delete v_1 and all its neighbors from G . We then pick another vertex v_2 , place it into A , and delete it and all its neighbors from G . We continue this process as long as we can. Note that no matter what, we definitely create an independent set at the end of this process, since the step where we delete all neighbors of v_i guarantees that no pair of vertices in A are adjacent. Moreover, as every vertex in G has degree less than \sqrt{n} , we delete at most \sqrt{n} vertices at each step of the process, and hence we can continue the process for at least $n/\sqrt{n} = \sqrt{n}$ steps. Thus, we end by producing an independent set A with $|A| \geq \sqrt{n}$.

We can thus split the proof of (4.1) into two lemmas. We denote by $\alpha(G)$ the *independence number* of G , that is, the size of the largest independent set in G .

Lemma 4.1.1. *If a triangle-free graph G has average degree d , then $\alpha(G) \geq d$.*

Lemma 4.1.2. *If an n -vertex graph G has average degree d , then $\alpha(G) \geq n/(1+d)$.*

Note that Lemma 4.1.1 follows directly from the argument above, since if the average degree is d , then certainly there is *some* vertex with degree at least d . In contrast, Lemma 4.1.2 actually *doesn't* follow from the above; the argument presented above only really works if G has *maximum* degree d . Nonetheless, Lemma 4.1.2 is true, and is one of the many equivalent formulations of Turán's theorem; you'll prove it on the homework. Note that in this lemma, and in the argument above, we didn't actually use the assumption that G is triangle-free—that assumption only came into Lemma 4.1.1, whereas the inductive procedure for building A works in any graph with bounded maximum degree.

The basic idea underlying the Ajtai–Komlós–Szemerédi theorem is that Lemma 4.1.2, while tight in general, is far from tight for triangle-free graphs. Basically, one can use the triangle-freeness to pick *intelligent* choices for v_i , which ensure that the process can continue for somewhat longer than the naïve analysis above suggests. A very slick formulation of this idea, due to Shearer [48], is the content of the following lemma.

Lemma 4.1.3 (Shearer [48]). *Define*

$$f(d) := \frac{d \ln d - d + 1}{(d-1)^2},$$

extended continuously to $f(0) := 1, f(1) := \frac{1}{2}$. If G is an n -vertex triangle-free graph with average degree d , then

$$\alpha(G) \geq n \cdot f(d) = (1 - o(1)) \frac{n \ln d}{d},$$

where the $o(1)$ tends to 0 as $d \rightarrow \infty$.

Proof. Note that $f(d) = (1 - o(1)) \frac{\ln d}{d}$, so it suffices to prove the first inequality. We prove the statement by induction on n , where for every fixed n we prove it simultaneously for all d . For the base case, note that the result is trivial if $n = 1$, as the only 1-vertex graph has no edges and $d = 0$, and independence number $1 = 1 \cdot f(0)$. We now proceed with the inductive step, and assume that the result has been proved for all smaller values of n .

For a vertex $v \in V(G)$, let us denote by $\deg(v)$ its degree, and by $r(v)$ the average degree of its neighbors, namely

$$r(v) := \frac{1}{\deg(v)} \sum_{u \sim v} \deg(u),$$

where $u \sim v$ denotes that u is adjacent to v . The reason we care about these quantities is that we plan to pick a carefully-chosen vertex v , and then define \widehat{G} to be the induced subgraph obtained by deleting v and all its neighbors. When we do this, we have that

$$v(\widehat{G}) = n - (\deg(v) + 1),$$

since we deleted $\deg(v) + 1$ vertices, and that

$$e(\widehat{G}) = e(G) - \sum_{u \sim v} \deg(u) = e(G) - \deg(v)r(v).$$

This is the only step in which we use that G is triangle-free, to ensure that indeed $\deg(v)r(v)$ edges are deleted—if there were triangles in the graph, then neighbors of v might be adjacent, and then this might be an overcount of the number of deleted edges. Recalling that the average degree of G is d , so that $e(G) = nd/2$, we compute that the average degree of \widehat{G} is

$$\widehat{d} = 2 \frac{e(\widehat{G})}{v(\widehat{G})} = 2 \frac{\frac{1}{2}nd - \deg(v)r(v)}{n - \deg(v) - 1} = \frac{nd - 2\deg(v)r(v)}{n - \deg(v) - 1}.$$

Let us note for future reference that

$$\begin{aligned} (n - \deg(v) - 1)(\widehat{d} - d) &= (nd - 2\deg(v)r(v)) - (nd - d\deg(v) - d) \\ &= d\deg(v) + d - 2\deg(v)r(v). \end{aligned} \quad (4.2)$$

Note that we may add v to any independent set in \widehat{G} to obtain an independent set in G , and therefore the inductive hypothesis implies that

$$\alpha(G) \geq 1 + \alpha(\widehat{G}) \geq 1 + (n - \deg(v) - 1)f(\widehat{d}).$$

One can check that $f''(x) \geq 0$ for all $x > 0$, which implies that

$$f(\widehat{d}) \geq f(d) + (\widehat{d} - d)f'(d).$$

Therefore, continuing the computation above, we have that

$$\begin{aligned} \alpha(G) &\geq 1 + (n - \deg(v) - 1)f(\widehat{d}) \\ &\geq 1 + (n - \deg(v) - 1)f(d) + (n - \deg(v) - 1)(\widehat{d} - d)f'(d) \\ &= 1 + (n - \deg(v) - 1)f(d) + (d\deg(v) + d - 2\deg(v)r(v))f'(d), \end{aligned} \quad (4.3)$$

where the final equality uses (4.2).

Recall that we have yet to pick v . From the computation above, it is clear that we should pick v so that $A(v) := (d\deg(v) + d - 2\deg(v)r(v))f'(d)$ is large relative to $B(v) := (\deg(v) + 1)f(d)$. In order to do this, let us compute the average values of both of these quantities, averaged over all $v \in V(G)$. The quantity B is easy, as

$$\frac{1}{n} \sum_{v \in V} (\deg(v) + 1)f(d) = (d + 1)f(d). \quad (4.4)$$

For the first quantity, we first compute that

$$\sum_{v \in V(G)} \deg(v)r(v) = \sum_{v \in V(G)} \sum_{u \sim v} \deg(u) = \sum_{u \in V(G)} \sum_{v \sim u} \deg(u) = \sum_{u \in V(G)} \deg(u)^2 \geq nd^2, \quad (4.5)$$

where the final inequality uses the Cauchy–Schwarz inequality and the assumption that the average degree in G is d . Therefore, the average value of $A(v)$ is

$$\frac{1}{n} \sum_{v \in V(G)} (d \deg(v) + d - 2 \deg(v)r(v)) f'(d) \leq (d^2 + d - 2d^2) f'(d) = (d - d^2) f'(d), \quad (4.6)$$

where we *reversed* the direction of the inequality from (4.5) because $f'(x) \leq 0$ for all $x > 0$. We now observe that the definition of f implies that it solves the differential equation

$$(d + 1)f(d) = 1 + (d - d^2)f'(d).$$

Thus, (4.4) and (4.6) imply that one plus the average value of $A(v)$ is at least the average value of $B(v)$. This implies that we can pick some vertex $v \in V(G)$ such that $1 + A(v) \geq B(v)$. Plugging this into (4.3) shows that

$$\begin{aligned} \alpha(G) &\geq 1 + (n - \deg(v) - 1)f(d) + (d \deg(v) + d - 2 \deg(v)r(v))f'(d) \\ &= 1 + nf(d) - B(v) + A(v) \\ &\geq nf(d), \end{aligned}$$

completing the proof. \square

Given this lemma, the proof of the improved upper bound on $r(3, k)$ is straightforward.

Theorem 4.1.4 (Ajtai–Komlós–Szemerédi [2], Shearer [48]). *With the function f as defined in Lemma 4.1.3, we have*

$$r(3, k) \leq \frac{k}{f(k)} = (1 + o(1)) \frac{k^2}{\ln k},$$

where the $o(1)$ term tends to 0 as $k \rightarrow \infty$.

Proof. Note that $f(k) = (1 + o(1)) \frac{\ln k}{k}$ as $k \rightarrow \infty$, so it suffices to prove the first inequality. Let $n = k/f(k)$. The statement that $r(3, k) \leq n$ is equivalent to saying that every n -vertex graph G contains a triangle or an independent set of order at least k . So fix an n -vertex graph, and let us assume that G is triangle-free (for otherwise we are done). If the average degree d of G is at least k , then we have $\alpha(G) \geq d \geq k$ by Lemma 4.1.1, so we may assume that $d < k$. Therefore, by Lemma 4.1.3 and the monotonicity of the function f , we have

$$\alpha(G) \geq nf(d) \geq nf(k) = k. \quad \square$$

We remark that a simple induction argument, together with (2.1), can be used to deduce from Theorem 4.1.4 that for any fixed s , we have

$$r(s, k) = O_s \left(\frac{k^{s-1}}{\log k} \right).$$

Ajtai, Komlós, and Szemerédi used the same idea, but with a more involved induction, to prove that in fact

$$r(s, k) = O_s \left(\frac{k^{s-1}}{(\log k)^{s-2}} \right).$$

This remains the best known upper bound on off-diagonal Ramsey numbers, and it may well be asymptotically best possible.

4.2 Interlude: an application to sphere packing

Before we continue the discussion of off-diagonal Ramsey numbers by seeing lower bounds on $r(3, k)$ and $r(4, k)$, let's discuss a recent and striking application of Lemma 4.1.3 (or rather, a strengthening of it) to a geometric problem.

A *sphere packing* in d dimensions is a collection of unit balls in \mathbb{R}^d whose interiors are disjoint. The *density* of a sphere packing is, informally, the fraction of \mathbb{R}^d that is contained in one of the spheres; more formally, if we let S be the union of the balls, then the density is

$$\theta(S) := \limsup_{N \rightarrow \infty} \frac{\text{vol}(S \cap [-N, N]^d)}{(2N)^d}.$$

The *sphere packing constant* in dimension d , denoted $\theta(d)$, is the supremum of $\theta(S)$ over all d -dimensional sphere packings; it captures the most efficient way of filling \mathbb{R}^d with disjoint unit balls.

The exact value of $\theta(d)$ is only known in dimensions $d \in \{1, 2, 3, 8, 24\}$. Dimension 1 is trivial, and dimension 2 was resolved by Thue in the 19th century; the triangular lattice gives the densest packing in \mathbb{R}^2 , which is what you would expect from playing around with circle packings. The correct answer in dimension 3 was conjectured by Kepler in 1611, but remained open for hundreds of years until finally being proved by Hales [30], via an extremely long and heavily computer-assisted proof; more recently, the proof was fully formalized in a proof assistant [29]. Even more recently, Viazovska [52] determined $\theta(8)$, and Cohn–Kumar–Miller–Radchenko–Viazovska determined $\theta(24)$. The densest packings in these dimensions are determined by very special lattices called the E_8 and Leech lattice, respectively.

For general dimensions, much less is known. There is a simple general lower bound of $\theta(d) \geq 2^{-d}$, which was improved by Rogers [43] to $\theta(d) = \Omega(d2^{-d})$. There have been a number of constant-factor improvements to this bound over the years, but no one was able to prove that $\theta(d) = \omega(d2^{-d})$ as $d \rightarrow \infty$. This changed very recently with a breakthrough of Campos, Jenssen, Michelen, and Sahasrabudhe [10], who improved Rogers' bound by a factor of $\Omega(\log d)$.

Theorem 4.2.1 (Campos–Jenssen–Michelen–Sahasrabudhe [10]).

$$\theta(d) \geq (1 - o(1)) \frac{d \ln d}{2^{d+1}}.$$

Their proof is too complicated (and too off-topic) to do in any sort of detail, but let's see a very rough sketch. They begin by randomly selecting a set of points $X \subset \mathbb{R}^d$, which will be potential centers of spheres in the packing. This random choice is done in a very carefully-defined manner, which we will not describe, but which ensures that X satisfies certain desirable properties. Having defined X , one can define a graph G_X whose vertex set is X , and where two vertices are adjacent if their Euclidean distance is less than 2. Because of this choice, an independent set in G_X is precisely a collection of centers of disjoint unit balls. Hence, the task boils down to proving a lower bound on $\alpha(G_X)$, which is where the connection to Lemma 4.1.3 comes in. Unfortunately, G_X is not triangle-free in general,

so Campos–Jenssen–Michelen–Sahasrabudhe proved a strengthening of Lemma 4.1.3 to the setting of graphs with “few” triangles (or, more precisely, to the setting when all pairs of vertices have few common neighbors).

Theorem 4.2.2 (Campos–Jenssen–Michelen–Sahasrabudhe [10]). *Let G be a graph with n vertices and maximum degree Δ . Suppose that every pair of distinct vertices in G has at most $\Delta/(2 \ln \Delta)^7$ common neighbors. Then*

$$\alpha(G) \geq (1 - o(1)) \frac{n \ln \Delta}{\Delta},$$

where the $o(1)$ tends to 0 as $\Delta \rightarrow \infty$.

The proof of Theorem 4.2.2 can be viewed as a generalization of the proof of Lemma 4.1.3. Basically, rather than deleting a single carefully-chosen v (as well as its neighbors) at every step, they instead pick a random set of $\varepsilon n / \Delta$ vertices at every step, and delete them and all their neighbors from G , where ε is a small constant. By carefully adding edges back to G after such a step, in order to ensure that the edge density stays constant, they can continue this process for $(1 - o(1)) \ln \Delta$ steps, and thus find the desired independent set.

4.3 Lower bounds on off-diagonal Ramsey numbers

Let us recall the statement of Lemma 3.1.1. It said that if G is a K_s -free graph on N vertices, such that the number of independent sets of order k is at most M^k , then

$$r(s, k) \geq \frac{N}{4M}.$$

Thus, in order to prove a lower bound on $r(3, k)$ (for example), we need to find a triangle-free graph G where we have good control over the number of independent sets of order k in G .

The tool we’ll use to estimate the number of independent sets of order k is the following result, which says that if a graph is “locally dense”—any reasonably large set contains many edges—then it has few independent sets of a given order. This specific lemma is due to Kohayakawa, Lee, Rödl, and Samotij [35], although the proof technique goes back to work of Kleitman and Winston [34], and the same idea was first applied in this setting by Alon and Rödl [3]. An excellent survey on this topic, including a detailed proof of Lemma 4.3.1, was written by Samotij [45].

Lemma 4.3.1. *Fix positive integers n, r, R and a parameter $\beta \in [0, 1]$, which satisfy $Re^{\beta r} \geq n$. Suppose that G is an n -vertex graph with the property that for every $X \subseteq V(G)$ with $|X| \geq R$, we have*

$$e(X) \geq \beta \frac{|X|^2}{2}.$$

Then for any $k \geq r$, the number of independent sets in G of order k is at most

$$rn^r \binom{R}{k-r}.$$

If $r \ll k$, then the term rn^r will be subexponential in k , whereas the binomial coefficient is at most $(eR/k)^k$. Thus, we are roughly in the setting of Lemma 3.1.1 with $M \approx R/k$.

Proof of Lemma 4.3.1. We run the following algorithm (called the Kletiman–Winston algorithm) to enumerate the independent sets of order k in G . At a given step of the algorithm, we have chosen some vertices v_1, \dots, v_i which are in our independent set, and we have a remaining set C_{i+1} of candidate vertices. We begin with $C_1 = V(G)$, and we stop the iteration if ever $|C_{i+1}| < R$.

At every step of the algorithm, we look at a maximal-degree vertex v in $G[C_{i+1}]$, the subgraph of G induced by C_{i+1} . As we have not yet stopped, we know that $|C_{i+1}| \geq R$, and therefore $e(C_{i+1}) \geq \beta \frac{|C_{i+1}|^2}{2}$ by assumption. Equivalently, this condition says that the average degree in $G[C_{i+1}]$ is at least $\beta|C_{i+1}|$. As v was chosen to have maximal degree in C_{i+1} , we conclude that

$$|N(v) \cap C_{i+1}| \geq \beta|C_{i+1}|.$$

We now decide whether to include v in our independent set. If yes, we set $v_{i+1} = v$ and $C_{i+2} = C_{i+1} \setminus N(v)$, to ensure that C_{i+2} is still a valid set of candidates for forming an independent set. If no, we discard v from C_{i+1} and repeat the process above with v replaced by a new maximum-degree vertex.

As stated above, we continue this process until $|C_{i+1}| < R$. At that point, we arbitrarily select $w_{i+1}, \dots, w_k \in C_{i+1}$ such that $\{v_1, \dots, v_i, w_{i+1}, \dots, w_k\}$ forms an independent set.

We claim that we can run this process only up to step r , that is, once we select v_1, \dots, v_r , our candidate set C_{r+1} has necessarily shrunk to $|C_{r+1}| < R$. Indeed, every time we select v_i , we have that

$$\frac{|C_{i+1}|}{|C_i|} = \frac{|C_i \setminus N(v_i)|}{|C_i|} \leq \frac{(1 - \beta)|C_i|}{|C_i|} = 1 - \beta.$$

Therefore,

$$|C_{r+1}| = \frac{|C_{r+1}|}{|C_r|} \cdot \frac{|C_r|}{|C_{r-1}|} \cdots \frac{|C_2|}{|C_1|} \cdot |C_1| \leq (1 - \beta)^r n < e^{-\beta r} n \leq R,$$

where the final inequality is our assumption that $Re^{\beta r} \geq n$.

Note that the procedure above necessarily generates every independent set of order k in G . Therefore, we can bound the number of such independent sets by estimating how many choices we have. The process may stop at any index $0 \leq i \leq r$, and we have at most n^i choices for v_1, \dots, v_i . At that point, as the candidate set has shrunk to size at most R , we have at most $\binom{R}{k-i}$ choices for w_{i+1}, \dots, w_k . Therefore, the total number of independent sets of order k in G is at most

$$\sum_{i=0}^r n^i \binom{R}{k-i}.$$

It is easy to see that the summand is maximized at $i = r$, and hence the total number is at most $r \cdot n^r \binom{R}{k-r}$, as claimed. \square

4.3.1 Lower bounds on $r(3, k)$

Given Lemma 4.3.1, our task is now to find a triangle-free graph that is locally dense, in the sense of satisfying Lemma 4.3.1 with appropriate parameters. The construction we present is inspired by work of Conlon [14, 15], but is not quite the same as his, and the analysis also uses ideas from [18, 39]. Several alternative constructions are presented in [5].

Let q be a prime power, and consider the finite field \mathbb{F}_q , as well as the three-dimensional vector space \mathbb{F}_q^3 over it. We begin by defining a bipartite graph Γ_q as follows. The vertex set of Γ_q has two parts P, L , whose names stand for *points* and *lines*. We identify P with \mathbb{F}_q^3 , and think of the vertices in P as points in this vector space. L , in turn, consists of all lines in \mathbb{F}_q^3 whose *direction* is of the form $(1, z, z^2)$, namely all lines of the form

$$\{x + y \cdot (1, z, z^2) : y \in \mathbb{F}_q\} \subseteq \mathbb{F}_q^3,$$

where $x \in \mathbb{F}_q^3$ and $z \in \mathbb{F}_q$. Note that there are exactly q^3 such lines, since we have q options for the direction (from the q options for z), and each such direction gives exactly q^2 parallel lines. Thus $|P| = |L| = q^3$. Finally, we define edges in Γ_q by incidence: we set a vertex $p \in P$ adjacent to a vertex $\ell \in L$ if and only if the point p lies on the line ℓ .

The first key fact we need about Γ_q is the following lemma.

Lemma 4.3.2. Γ_q is C_4 -free and C_6 -free.

Proof. First suppose that there is a C_4 in Γ_q . As Γ_q is bipartite, this means that there are distinct $p_1, p_2 \in P, \ell_1, \ell_2 \in L$ such that p_1, p_2 are both incident to both ℓ_1, ℓ_2 . But this is impossible, as any two lines in \mathbb{F}_q^3 intersect in at most one point. (This is what we expect from our geometric intuition in \mathbb{R}^3 , and it's not hard to prove that the same holds in \mathbb{F}_q^3 .)

Similarly, if there is a C_6 in Γ_q , then there exist distinct $p_1, p_2, p_3 \in P$ and $\ell_1, \ell_2, \ell_3 \in L$ such that p_i and p_{i+1} are both incident to ℓ_i for all i , where the indices are taken modulo 3. Let $z_1, z_2, z_3 \in \mathbb{F}_q$ be such that ℓ_i has direction $(1, z_i, z_i^2)$ for $i \in [3]$. Then as both p_i and p_{i+1} are on line ℓ_i , we see that $p_i - p_{i+1}$ is a non-zero multiple of $(1, z_i, z_i^2)$, say $p_i - p_{i+1} = y_i \cdot (1, z_i, z_i^2)$ for some non-zero y_1, y_2, y_3 . Therefore,

$$0 = (p_1 - p_2) + (p_2 - p_3) + (p_3 - p_1) = \sum_{i=1}^3 y_i \cdot (1, z_i, z_i^2).$$

In other words, we've found that the vectors $\{(1, z_i, z_i^2)\}_{i=1}^3$ are linearly dependent. However, the well-known Vandermonde determinant formula implies that this is impossible unless $z_i = z_j$ for some $i \neq j$. But, for example, if $z_1 = z_2$, then this means that ℓ_1 and ℓ_2 are parallel. But as they both pass through p_2 , they must be the same line, a contradiction. The same argument applies if $z_2 = z_3$ or $z_1 = z_3$, and we conclude that Γ_q is C_6 -free. \square

We now (randomly) define a graph G_q as follows. The vertex set of G_q is L , the second vertex part of Γ_q . The edges of G_q are defined as follows. For each $p \in P$, let $N(p)$ denote the neighborhood of p in Γ_q , i.e. the set of lines in L incident to p . For each $p \in P$, we pick a uniformly random bipartition of $N(p)$ into $A(p) \sqcup B(p)$. Then, for every $\ell_1 \in A(p), \ell_2 \in B(p)$,

we add an edge between ℓ_1 and ℓ_2 in G_q . Doing this for all $p \in P$, we obtain the random graph G_q . In other words, G_q is the edge-union of complete bipartite graphs, where each $p \in P$ contributes a complete bipartite graph between $A(p)$ and $B(p)$.

Recall that Γ_q is C_4 -free by Lemma 4.3.2. This means that for every $\ell_1, \ell_2 \in L$, there is at most one choice of p such that $\ell_1, \ell_2 \in N(p)$. Hence, to every edge $(\ell_1, \ell_2) \in E(G_q)$, we can associate a *label* p , which is the unique $p \in P$ such that $\ell_1, \ell_2 \in N(p)$.

Lemma 4.3.3. *G_q is triangle-free with probability 1 (i.e. regardless of the random choices).*

Proof. Suppose for contradiction that there exist distinct $\ell_1, \ell_2, \ell_3 \in L = V(G_q)$ that form a triangle in G_q . Let $p_1, p_2, p_3 \in P$ be the labels of (ℓ_1, ℓ_2) , (ℓ_2, ℓ_3) , and (ℓ_3, ℓ_1) , respectively.

We split into two cases. First, suppose that two of the p_i are equal, say $p_1 = p_2$. This implies that ℓ_1, ℓ_2, ℓ_3 all lie in $N(p_1)$. This then implies that $p_3 = p_1$ as well. But recall that the only edges we add with label p_1 are a complete bipartite graph between $A(p_1)$ and $B(p_1)$, and these edges can contain no triangle as this graph is bipartite. This concludes this case.

So we may now assume that p_1, p_2, p_3 are distinct. But then the fact that $\ell_i, \ell_{i+1} \in N(p_i)$ for all $i \in \llbracket 3 \rrbracket$ implies that $\ell_1, p_1, \ell_2, p_2, \ell_3, p_3$ forms a copy of C_6 in Γ_q . By Lemma 4.3.2 no such copy can exist, a contradiction. \square

The final result we need about G_q is that it satisfies the local density condition we need to apply Lemma 4.3.1. It is here where the randomness in the definition of G_q is crucial. We first prove that for any large set of vertices X of G_q , there are many “potential edges” of G_q , namely many pairs $\ell_1, \ell_2 \in X$ such that $\ell_1, \ell_2 \in N(p)$ for some $p \in P$. Once we have this, the randomness will imply that a good fraction of these potential edges will become true edges of G_q .

Lemma 4.3.4. *For any $X \subseteq L$, the number of pairs $(\ell_1, \ell_2) \in X^2$ such that $\ell_1, \ell_2 \in N(p)$ for some $p \in P$ is at least $|X|^2/q$.*

Proof. The quantity we are interested in is precisely

$$\sum_{p \in P} |N(p) \cap X|^2.$$

By the Cauchy–Schwarz inequality, we have

$$\sum_{p \in P} |N(p) \cap X|^2 \geq \frac{1}{|P|} \left(\sum_{p \in P} |N(p) \cap X| \right)^2.$$

Note that the quantity in parentheses is precisely the number of edges in Γ_q incident to $X \subseteq L$. Since every vertex in L is incident to precisely q edges (as every line in \mathbb{F}_q^3 contains exactly q points), we have that

$$\frac{1}{|P|} \left(\sum_{p \in P} |N(p) \cap X| \right)^2 = \frac{1}{|P|} \left(\sum_{\ell \in X} q \right)^2 = \frac{1}{q^3} (q|X|)^2 = \frac{|X|^2}{q},$$

where we also plug in that $|P| = q^3$. \square

Since Lemma 4.3.4 counts unordered pairs (ℓ_1, ℓ_2) , we find that X contains at least $|X|^2/(2q)$ “potential edges”. On average, a set $X \subseteq L$ will keep roughly half of its “potential edges” when we sample the random graph G_q . The reason is that each potential edge corresponds to a pair $\ell_1, \ell_2 \in N(p)$ for some p , and there is a probability $1/2$ that these two vertices will be placed on opposite sides of the bipartition $A(p) \cup B(p)$, thus yielding a true edge in G_q . Of course, not every set X will receive *exactly* half of its potential edges, and we expect some random fluctuations. Nonetheless, it is intuitively reasonable that all *large* sets X will receive roughly half of the potential edges, and thus we expect to be in the setting of Lemma 4.3.1 with the parameter $\beta \approx 1/(2q)$.

Before making this formal, let’s think about how small of an X we can expect this to hold for. Note that in G_q , a typical vertex ℓ has $\Theta(q^2)$ neighbors. The reason is that ℓ lies in $N(p)$ for exactly q choices of p , and each such p will yield, on average, $|N(p)|/2 = \Theta(q)$ edges of G_q incident to ℓ . As G_q is triangle-free, clearly the neighborhood of any ℓ must actually contain *zero* edges. Hence, we cannot expect $e(X) \geq \beta|X|^2/2$ to hold for all sets X of order $\Theta(q^2)$. Thus, again using the terminology of Lemma 4.3.1, we should expect to pick R of order at least q^2 .

In fact, one can really obtain such a result with $R = \Theta(q^2)$, as noted in [39, Section 3]. However, doing this requires a somewhat involved argument based on a certain dyadic partitioning. We will prove the following weaker statement, which establishes that we are in the setting of Lemma 4.3.1 with $R = \Theta(q^2 \log q)$ and $\beta = \Theta(1/q)$.

Lemma 4.3.5. *With positive probability, G_q has the following property.. For every $X \subseteq L$ with $|X| \geq R := 200q^2 \ln q$, we have that*

$$e(X) \geq \beta \frac{|X|^2}{2},$$

where $\beta := 1/(10q)$.

Proof of Lemma 4.3.5

For the proof, we will need the following probabilistic concentration inequality, which is a convenient form of the Azuma–Hoeffding inequality. A proof can be found in [32, Corollary 2.27 and Remark 2.28] or [4, Section 7.2]. Let us say that a function $f : \{0, 1\}^m \rightarrow \mathbb{R}$ is $\{L_i\}$ -Lipschitz if its value changes by at most L_i whenever the input is changed on only the i th coordinate, that is, for all $i \in [m]$ and all $z_1, \dots, z_m \in \{0, 1\}$, we have

$$|f(z_1, \dots, z_i, \dots, z_m) - f(z_1, \dots, 1 - z_i, \dots, z_m)| \leq L_i.$$

Lemma 4.3.6. *Let Z_1, \dots, Z_m be independent random variables taking values in $\{0, 1\}$. Let $f : \{0, 1\}^m \rightarrow \mathbb{R}$ be $\{L_i\}$ -Lipschitz, and let $Z = f(Z_1, \dots, Z_m)$. Then*

$$\Pr \left(Z \leq \frac{1}{2} \mathbb{E}[Z] \right) \leq \exp \left(- \frac{\mathbb{E}[Z]^2}{2 \sum_{i=1}^m L_i^2} \right).$$

With this in hand, we are ready to prove Lemma 4.3.5.

Proof of Lemma 4.3.5. First, let us fix some set $X \subseteq L$ with $|X| \geq R$. For every $\ell \in X$ and every $p \in P$ such that $\ell \in N(p)$, let us make a random variable $Z_{\ell,p}$ with value 1 if $\ell \in A(p)$, and value 0 if $\ell \in B(p)$. Let $Z = e(X)$, which is a random variable depending on the random choices of the bipartition. In fact, we see that Z is a function of the random variables $Z_{\ell,p}$. Note that flipping $Z_{\ell,p}$ corresponds to changing whether $\ell \in A(p)$ or $\ell \in B(p)$, and this can affect the number of edges in X by at most $|N(p) \cap X|$. Hence, this function is Lipschitz with parameters

$$L_{\ell,p} := |N(p) \cap X|.$$

From the proof of Lemma 4.3.4, we see that $S := \sum_{\ell,p} L_{\ell,p}^2$ is precisely equal to the number of pairs $(\ell_1, \ell_2) \in X^2$ with $\ell_1, \ell_2 \in N(p)$ for some $p \in P$.

We now claim that $\mathbb{E}[Z] \geq \frac{1}{5}S \geq |X|^2/(5q)$, where the final inequality is simply the statement of Lemma 4.3.4. The reason is that, as discussed above, every unordered pair of distinct ℓ_1, ℓ_2 counted by S becomes an edge of G_q with probability $\frac{1}{2}$. S counts ordered pairs, so we need to divide by 2, and need to subtract off the contribution of $|X|$ pairs (ℓ, ℓ) . But since $|X| \geq R > 10q$, the number of such pairs is at most $S/10$.

Therefore, by Lemma 4.3.6 and the definition of β , we find that

$$\begin{aligned} \Pr \left(e(X) < \beta \frac{|X|^2}{2} \right) &\leq \Pr \left(Z \leq \frac{1}{2} \mathbb{E}[Z] \right) \\ &\leq \exp \left(-\frac{\mathbb{E}[Z]^2}{2S} \right) \\ &\leq \exp \left(-\frac{\mathbb{E}[Z]}{10} \right) \\ &\leq \exp \left(-\frac{|X|^2}{50q} \right) \end{aligned}$$

We may now take a union bound over the $\binom{q^3}{|X|}$ choices for such an X , and sum this up over all choices of $|X|$, to find that the probability that the claimed property does not hold is at most

$$\sum_{|X|=R}^{q^3} \binom{q^3}{|X|} e^{-|X|^2/(50q)} \leq \sum_{|X|=R}^{q^3} q^{3|X|} e^{-|X|^2/(50q)} = \sum_{|X|=R}^{q^3} \left(e^{3 \ln q - |X|/(50q)} \right)^{|X|}.$$

Note that our choice of $R = 200q^2 \ln q$ implies that

$$e^{3 \ln q - |X|/(50q)} \leq e^{3 \ln q - R/(50q)} \leq \frac{1}{q}.$$

Hence, the sum above is at most $2q^{-R}$, which is less than 1. Thus, G_q has the claimed property with positive probability. \square

We are finally ready to deduce a lower bound on $r(3, k)$.

Theorem 4.3.7. *We have*

$$r(3, k) > \frac{k^2}{C(\log k)^3}$$

for an absolute constant $C > 0$.

By being more careful (specifically, by proving a version of Lemma 4.3.5 without the logarithmic loss in the value of R), one can improve this result to $r(3, k) = \Omega(k^2/(\log k)^2)$. It is not known whether one can use such a technique to obtain the optimal result, of $r(3, k) = \Omega(k^2/\log k)$.

Proof. By Bertrand's postulate, we can find a prime power q satisfying $k/(60(\ln k)^2) \leq q \leq k/(30(\ln k)^2)$, which implies that $k \geq 30q(\ln q)^2$. By Lemmas 4.3.3 and 4.3.5, we have the existence of a graph G_q on $n := q^3$ vertices with the properties that (a) G_q is triangle-free, and (b), G_q satisfies the conditions of Lemma 4.3.1 with $R = 200q^2 \ln q$ and $\beta = 1/(10q)$. Let $r := 10q \ln q$, and note that

$$Re^{\beta r} = (200q^2 \ln q)e^{(10q \ln q)/(10q)} = 200q^3 \ln q \geq n.$$

We also have that $k \geq 3r \ln q$, which implies that $k \geq r$ and that $n^r = q^{3r} \leq e^k$. We are in a position to apply Lemma 4.3.1. We conclude that the number of independent sets in G of order k is at most

$$rn^r \binom{R}{k-r} \leq \left(\frac{e^2 R}{k}\right)^k \leq \left(\frac{200e^2 q^2 \ln q}{30q(\ln q)^2}\right)^k \leq \left(\frac{50q}{\ln q}\right)^k.$$

We may therefore apply Lemma 3.1.1 with $N = n = q^3$ and $M = 50q/\ln q$, and conclude that

$$r(3, k) \geq \frac{N}{4M} = \frac{q^3}{200q/\ln q} = \frac{q^2 \ln q}{200} \geq 10^{-6} \frac{k^2}{(\ln k)^3}. \quad \square$$

4.3.2 Lower bounds on $r(4, k)$

Given everything we have done so far, it becomes very simple to explain the new ingredient introduced by Mattheus and Verstraëte to obtain a good lower bound on $r(4, k)$. Of course, this is really doing them a disservice, since the presentation above is heavily inspired by their work, and a major contribution of theirs is realizing how to implement such an approach.

The key new ingredient we need is a construction of a graph Λ_q , which is also a point-line incidence graph in a certain finite geometry, which does not contain the so-called *O'Nan configuration*. In graph-theoretic terms, this is simply a *subdivision* of K_4 , and can be explicitly described as a set of four distinct lines ℓ_1, \dots, ℓ_4 and four distinct points $p_{12}, p_{13}, p_{23}, p_{24}, p_{34}$ such that each p_{ij} is incident to both ℓ_i and ℓ_j .

We fix a prime power q , and work over the finite field \mathbb{F}_{q^2} and in the two-dimensional vector space $\mathbb{F}_{q^2}^2$ over it. Note that this is also, of course, a four-dimensional vector space over \mathbb{F}_q , but we won't think of it like this; our base field will always be \mathbb{F}_{q^2} , and then when we discuss e.g. lines, we will always mean one-dimensional \mathbb{F}_{q^2} -affine-linear subspaces. We define a map $\sigma : \mathbb{F}_{q^2}^2 \times \mathbb{F}_{q^2}^2 \rightarrow \mathbb{F}_{q^2}$ by

$$\sigma((a_1, a_2), (b_1, b_2)) = a_1 b_1^q + a_2 b_2^q.$$

We define

$$P := \{x \in \mathbb{F}_{q^2}^2 : \sigma(x, x) = -1\} = \{(x_1, x_2) \in \mathbb{F}_{q^2}^2 : x_1^{q+1} + x_2^{q+1} + 1 = 0\} \subseteq \mathbb{F}_{q^2}^2.$$

One can show that $|P| = (1 + o(1))q^3$; there are q^2 choices for x_1 , and having fixed x_1 , there are $(1 + o(1))q$ choices for a $(q + 1)$ th root of $-1 - x_1^{q+1}$, that is, $(1 + o(1))q$ choices for x_2 .

We also define L to consist of all lines in $\mathbb{F}_{q^2}^2$ which intersect P in at least two points. There are $(1 + o(1))q^4$ lines in $\mathbb{F}_{q^2}^2$, and one can show that at most q^3 of them intersect P in fewer than two points, so $|L| = (1 + o(1))q^4$. We define Λ_q to be the incidence graph between P and L , i.e. the bipartite graph with parts $P \cup L$, in which a pair (p, ℓ) is an edge if and only if p lies in the line ℓ .

The following lemma, which is analogous to Lemma 4.3.2, shows that this is a good graph to use for lower-bounding $r(4, k)$ using the technique discussed above. This result was first proved by O’Nan [41], which is why O’Nan configurations are so named.

Lemma 4.3.8. *The graph Λ_q is C_4 -free and contains no O’Nan configuration.*

The fact that Λ_q is C_4 -free follows from the exact same reason as in Lemma 4.3.2. Namely, a C_4 in Λ_q would correspond to two lines intersecting in two distinct points, and that cannot happen. The proof that Λ_q has no O’Nan configuration is also based on elementary linear algebra—just as the proof in Lemma 4.3.2 that Γ_q is C_6 -free—but we will skip it because it is somewhat more involved and not particularly interesting. An elementary proof can be found in [39, Proposition 1].

We now form a random graph H_q on vertex set L by picking, for each $p \in P$, a random bipartition $N(p) = A(p) \cup B(p)$ of its neighborhood in Λ_q , and adding to H_q all edges between $A(p)$ and $B(p)$. From Lemma 4.3.8, it is not hard to prove that H_q is K_4 -free with probability 1, just as in Lemma 4.3.3. The final ingredient we need, analogously to Lemma 4.3.5, is the following statement.

Lemma 4.3.9. *With positive probability, H_q has the following property. For every $X \subseteq L$ with $|X| \geq R := 10^7 q^2$, we have that*

$$e(X) \geq \beta \frac{|X|^2}{2},$$

where $\beta := 1/(300q)$.

Unfortunately, for technical reasons arising from the fact that $|L| \approx q^4$ is much larger than $|P| \approx q^3$, it seems impossible to prove Lemma 4.3.9 (or even a weaker version with some logarithmic losses) by blindly following the proof of Lemma 4.3.5. Instead, one has to partition P into three parts, depending on how large $|N(p) \cap X|$ is, and then apply the argument of Lemma 4.3.5 to each part in turn. As such, we will skip the proof; it can be found in [39, Theorem 3]. A somewhat more general (and somewhat simpler) result, with a logarithmic loss in the value of R , is proved in [18, Lemma 2].

However, once we have these preliminaries, we can follow the proof technique used above for $r(3, k)$. Namely, we can plug Lemma 4.3.9 into Lemma 4.3.1 to bound the number of

independent sets of order k there are in H_q , and then plug that result into Lemma 3.1.1. Doing this yields the theorem of Mattheus and Verstraëte [39].

Theorem 4.3.10 (Mattheus–Verstraëte [39]). *We have*

$$r(4, k) > \frac{k^3}{C(\log k)^4}$$

for an absolute constant $C > 0$.

Chapter 5

Graph Ramsey numbers

5.1 Introduction

We will now move away to a more general topic than we have considered so far, that of *graph Ramsey numbers*.

Definition 5.1.1. Given graphs H_1, \dots, H_q , their *Ramsey number* $r(H_1, \dots, H_q)$ is defined as the minimum N such that any q -coloring of $E(K_N)$ contains a monochromatic copy of H_i in color i , for some $i \in \llbracket q \rrbracket$. Here, by a monochromatic copy, we mean a subgraph of K_N isomorphic to H_i , all of whose edges receive color i .

In case $H_1 = \dots = H_q = H$, we denote this Ramsey number by $r(H; q)$. In case $q = 2$, we use the shorthand $r(H) := r(H; 2)$.

Of course, everything we have studied so far is a special case of these more general graph Ramsey numbers, as $r(k)$ is simply $r(K_k)$, and $r(k, \ell) = r(K_k, K_\ell)$, etc. However, it turns out that there is an extremely rich theory of Ramsey numbers of graphs H which are not necessarily complete graphs; moreover, most of the interesting results actually arise when H is extremely far from being a complete graph.

We begin with a simple observation, which is that if H_i is a subgraph of H'_i , then $r(H_1, \dots, H_q) \leq r(H'_1, \dots, H'_q)$, since any monochromatic copy of H'_i also yields a monochromatic copy of H_i . Thus, $r(H) \leq r(H')$ whenever $H \subseteq H'$. Since every n -vertex graph is a subgraph of K_n , we conclude that

$$r(H) \leq r(K_n) < 4^n \quad \text{for every } n\text{-vertex graph } H.$$

Thus, in the worst case, an n -vertex graph may have Ramsey number that is exponential in n .

On the other hand, the most general lower bound we can get is that $r(H) \geq n$ if H is an n -vertex graph. Indeed, we need at least n vertices to be able to “fit” a copy of H . Moreover, this trivial lower bound is best possible in general, for if H has no edges (or even one edge), then $r(H) = n$.

Thus, for a general n -vertex graph H , we know $n \leq r(H) \leq 4^n$, and both behaviors—linear in n and exponential in n —are possible, for the empty graph and the complete graph, respectively. Based on our experience for cliques, we might expect that the exponential bound should be closer to the truth for most graphs. However, the striking result that we will see is that for many “natural” classes of graphs—and, in fact, for all *sparse* graphs—the lower bound is much closer to the truth.

5.2 Ramsey numbers of trees

Let us begin with the following simple result, which was probably first observed by Erdős and Graham [21]; it says that the lower bound is close to tight for trees.

Theorem 5.2.1. *If T is an n -vertex tree, then $r(T) \leq 4n - 3$.*

To prove this, we will use two simple lemmas from elementary graph theory.

Lemma 5.2.2. *If a graph G has average degree d , then it has a subgraph G' with minimum degree at least $d/2$.*

Proof. Let G have m vertices, so that it has $md/2$ edges. Repeatedly delete from G a vertex of degree less than $d/2$, as long as such a vertex exists. Since we delete fewer than $d/2$ edges at each step, and continue for at most m steps, we delete fewer than $md/2$ edges in total. As G has exactly $md/2$ edges, when we terminate this process, there must be at least one edge—and thus at least one vertex—remaining. However, the process only terminates once we’ve produced a subgraph of minimum degree at least $d/2$, completing the proof. \square

Lemma 5.2.3. *Let T be an n -vertex tree. If G is a graph with minimum degree at least $n - 1$, then $T \subseteq G$.*

Proof. We proceed by induction on n , with the base case $n = 1$ being trivial since the only 1-vertex tree is a subgraph of every non-empty graph. Inductively, suppose this is true for all $(n - 1)$ -vertex trees. Let T' be obtained from T by deleting a leaf v , and let u be the unique neighbor of v in T . By the inductive hypothesis, $T' \subseteq G$, so let us pick a copy of T' in G , and let w be the vertex of G filling the role of u . As G has minimum degree at least $n - 1$, w has at least $n - 1$ neighbors, and at most $n - 2$ of these neighbors were used in embedding the other $n - 2$ vertices of T' . Thus, there is at least one unused neighbor of w , which means that we can extend the T' -copy to a T -copy by adding in this unused neighbor. \square

With this lemmas, it is straightforward to prove Theorem 5.2.1.

Proof of Theorem 5.2.1. Let $N = 4n - 3$, and fix a 2-coloring of $E(K_N)$. Without loss of generality, we may assume that at least half the edges are red. Let $G \subseteq K_N$ be the graph comprising the red edges. Since G has at least half the edges of K_N , it has average degree at least $2n - 2$. By Lemma 5.2.2, there is a subgraph $G' \subseteq G$ of minimum degree at least $n - 1$. By Lemma 5.2.3, we have $T \subseteq G'$, and this yields a monochromatic red copy of T . \square

5.3 Ramsey numbers of complete bipartite graphs

Recall that $K_{s,t}$ denotes the *complete bipartite graph* with parts of sizes s, t . We will always assume, without loss of generality, that $s \leq t$. Let us begin by proving the following upper bound on $r(K_{s,t})$.

Theorem 5.3.1. *For any $s \leq t$, we have*

$$r(K_{s,t}) \leq 2^{s+1}t.$$

Note that, if we plug in $s = t = n$, then we obtain that $r(K_{n,n}) = O(n2^n)$. Since $K_{n,n}$ has $2n$ vertices, this is a much better, although still exponential, bound than the naïve one of

$$r(K_{n,n}) \leq r(2n) < 4^{2n} = 16^n.$$

We remark that $r(K_{n,n})$ really does grow exponentially in n , and that the lower bound

$$r(K_{n,n}) > 2^{\frac{n-1}{2}}$$

will follow from a more general result, Proposition 5.4.1, which we will prove shortly. On the other hand, if we think of s as a constant, we obtain that $r(K_{s,t}) = O_s(t)$ as $t \rightarrow \infty$. Since $K_{s,t}$ has $s + t \leq 2t$ vertices, this shows that for fixed s , $K_{s,t}$ has a Ramsey number which is linear in its number of vertices—the same behavior as we saw for trees.

Proof of Theorem 5.3.1. In case $s = 1$, the claimed bound follows from Theorem 5.2.1, since $K_{1,t}$ is a tree. We henceforth assume that $t \geq s \geq 2$.

Let $N = 2^{s+1}t$, and fix a red/blue coloring of $E(K_N)$. For every vertex $v \in V(K_N)$, let $\deg_R(v), \deg_B(v)$ denote the red and blue degrees, respectively, of v . Let S denote the number of monochromatic copies of $K_{1,s}$ in the coloring. We can count S by summing over all N choices for the central vertex, and then picking s distinct neighbors; this shows that

$$S = \sum_{v \in V(G)} \left(\binom{\deg_R(v)}{s} + \binom{\deg_B(v)}{s} \right).$$

Note that $\deg_R(v) + \deg_B(v) = N - 1$ for every v , and that the sum $\binom{x}{s} + \binom{N-1-x}{s}$ is minimized¹ when $x = N - 1 - x$, i.e. $x = \frac{N-1}{2}$. Therefore, we find that

$$S \geq N \cdot 2 \binom{\frac{N-1}{2}}{s}.$$

On the other hand, another way of counting S is by counting over all options for the s leaves of the star. Let us assume for contradiction that there is no monochromatic $K_{s,t}$. Then

¹This is a special case of a much more general fact, that the function $x \mapsto \binom{x}{s}$ is convex for any fixed $s \geq 1$. This special case can also be proved directly without appealing to convexity.

every s -set of vertices forms the set of leaves of fewer than t red stars $K_{1,s}$, and of fewer than t blue stars $K_{1,s}$. Thus,

$$S < 2t \binom{N}{s}.$$

Comparing our lower and upper bounds on S , we find that

$$2t \binom{N}{s} > 2N \binom{\frac{N-1}{2}}{s}$$

or equivalently

$$t \cdot N(N-1) \cdots (N-s+1) > N \cdot \frac{N-1}{2} \left(\frac{N-1}{2} - 1 \right) \cdots \left(\frac{N-1}{2} - s + 1 \right).$$

Rearranging, this is equivalent to

$$\frac{2^s t}{N} > \left(\frac{N-1}{N} \right) \left(\frac{N-3}{N-1} \right) \left(\frac{N-5}{N-2} \right) \cdots \left(\frac{N-2s+1}{N-s+1} \right) = \prod_{i=0}^{s-1} \frac{N-2i-1}{N-i}.$$

However, we have that

$$\prod_{i=0}^{s-1} \frac{N-2i-1}{N-i} = \prod_{i=0}^{s-1} \left(1 - \frac{i+1}{N-i} \right) \geq 1 - \sum_{i=0}^{s-1} \frac{i+1}{N-i} \geq 1 - \frac{2 \binom{s+1}{2}}{N} \geq \frac{1}{2},$$

where the first inequality uses that $N \geq 2s$, hence $N-i \geq N/2$ for all $i \leq s-1$, and the second inequality uses that $2 \binom{s+1}{2} = (s+1)s \leq (s+1)t \leq 2^s t = N/2$, since $2^s \geq s+1$ for all $s \geq 2$. Putting this all together, we conclude that

$$\frac{2^s t}{N} > \frac{1}{2},$$

which contradicts our choice of N . This contradiction completes the proof. \square

In fact, if one carefully examines the proof of Theorem 5.3.1, it becomes evident that we are not *really* using the fact that there are two colors. Instead, all we are really doing is noticing that any graph with sufficiently many edges must contain a copy of $K_{s,t}$. Such a result was first proved by Kővári, Sós, and Turán [36], and it has become one of the most fundamental results in extremal graph theory; they also introduced the technique which we used in the proof of Theorem 5.3.1.

Theorem 5.3.2 (Kővári–Sós–Turán [36]). *Let $s \leq t$ be integers, and let G be an N -vertex graph with at least $t^{\frac{1}{s}} N^{2-\frac{1}{s}} + sN$ edges. Then $K_{s,t}$ is a subgraph of G .*

Proof. Let d be the average degree of G , and note that

$$d = \frac{2e(G)}{N} \geq 2t^{\frac{1}{s}} N^{1-\frac{1}{s}}. \quad (5.1)$$

Also, since $e(G) \geq sN$, we have that $d \geq 2s$. For a real number x , we define

$$f(x) = \begin{cases} \frac{x(x-1)\dots(x-s+1)}{s!} & \text{if } x \geq s-1 \\ 0 & \text{otherwise.} \end{cases}$$

The function f is convex (this can be verified by computing its second derivative), and agrees with the binomial coefficient $\binom{x}{s}$ whenever x is a non-negative integer. Note too that since $d \geq 2s$, we have

$$f(d) = \frac{1}{s!} \cdot d(d-1)\dots(d-s+1) \geq \frac{1}{s!} \cdot \left(\frac{d}{2}\right)^s = \frac{d^s}{2^s s!}. \quad (5.2)$$

Let S denote the number of copies of $K_{1,s}$ in G . We can count S by summing over all N choices for the central vertex, and then picking s distinct neighbors; this shows that

$$S = \sum_{v \in V(G)} \binom{\deg(v)}{s} = \sum_{v \in V(G)} f(\deg(v)).$$

Now, since f is convex, Jensen's inequality and (5.2) imply that

$$S \geq N \cdot f(d) \geq \frac{Nd^s}{2^s s!}.$$

On the other hand, another way of counting S is by counting over all options for the s leaves of the star. Let us assume for contradiction that $K_{s,t} \not\subseteq G$. Then every s -set of vertices forms the set of leaves of fewer than t stars $K_{1,s}$. Hence,

$$S < \binom{N}{s} t \leq \frac{N^s t}{s!}.$$

Comparing the lower and upper bounds on S , we find that

$$\frac{Nd^s}{2^s} < N^s t,$$

or equivalently

$$d < 2t^{\frac{1}{s}} N^{1-\frac{1}{s}}.$$

This contradicts (5.1), completing the proof. □

5.4 The Burr–Erdős conjecture

So far, we have seen several examples of graph Ramsey numbers, and observed different growth rates. First, as we know from Chapter 2, $r(K_n)$ grows exponentially in n . Similarly, $r(K_{n,n})$ grows exponentially in n (and thus in $2n$, which is its number of vertices). On the other hand, all trees, as well as complete bipartite graphs in which one side has constant size, have Ramsey numbers *linear* in the number of vertices. Can we figure out a general rule explaining these extremely different growth rates?

Looking at the examples above, it is natural to guess that the major difference has to do with *density*. Both K_n and $K_{n,n}$ are very dense graphs, namely graphs with a quadratic number of edges. On the other hand, trees and complete bipartite graphs with one side of constant size are very sparse, in that their number of edges is only linear in their number of vertices. Equivalently, the average degree of the former graphs is large—linear in the number of vertices—whereas it is *constant* for the latter graphs. Perhaps this explains the difference in the Ramsey numbers?

As it turns out, this is close to the correct explanation. One direction really is true; if a graph has high average degree, then its Ramsey number is large, as shown in the following simple proposition.

Proposition 5.4.1. *If H has average degree d , then $r(H) > 2^{\frac{d-1}{2}}$.*

Proof. The proof is very similar to that of Theorem 2.2.2. Let H have $k \geq 2$ vertices, and thus $kd/2$ edges. Let $N = 2^{\frac{d-1}{2}}$, and consider a uniformly random 2-coloring of $E(K_N)$. Every tuple of k vertices in K_N forms a monochromatic copy of H with probability $2^{1-kd/2}$, and there are $k! \binom{N}{k}$ such tuples². Therefore, the probability that the coloring has a monochromatic copy of H is at most

$$k! \binom{N}{k} \cdot 2^{1-\frac{kd}{2}} < N^k \cdot 2^{1-\frac{kd}{2}} = 2^{k\frac{d-1}{2} + 1 - \frac{kd}{2}} = 2^{1-\frac{k}{2}} \leq 1,$$

and thus there must exist a coloring with no monochromatic copies of H . \square

Thus, we find that if H has average degree which is linear in its number of vertices $v(H)$, then $r(H)$ is exponential in $v(H)$. Is it possible that the same holds at the opposite extreme, namely that if H has constant average degree, then $r(H)$ is linear in $v(H)$, as happened for trees and complete bipartite graphs? It is not hard to see that the answer is no.

Proposition 5.4.2. *There exists an n -vertex graph H with average degree at most 1 and with $r(H) > 2^{\sqrt{n}/2}$.*

Proof. Let H be obtained from a complete graph $K_{\sqrt{n}}$ by adding $n - \sqrt{n}$ isolated vertices. Then H has $\binom{\sqrt{n}}{2}$ edges, and thus average degree $\frac{2}{n} \binom{\sqrt{n}}{2} \leq 1$. However,

$$r(H) \geq r(K_{\sqrt{n}}) > 2^{\sqrt{n}/2},$$

²Note that we include an extra factor of $k!$, which was not present in the proof of Theorem 2.2.2. The reason is that K_k is highly symmetric; for a general H , we need to consider not only the k vertices that can define it, but also the potentially $k!$ different ways of identifying $V(H)$ with these k vertices.

by Theorem 2.2.2. □

Given this example, it's clear why the naïve conjecture “constant average degree implies linear Ramsey number” cannot be true. Namely, the graph H above has constant average degree, but it contains a subgraph (namely $K_{\sqrt{n}}$) with much higher average degree, and it is this subgraph that really determines $r(H)$. This shows that rather than considering the global average degree, we need to consider a more refined parameter that takes into account subgraphs that are denser than H itself. There are several different ways of formalizing such a parameter, and they end up giving essentially identical results; we will use the following.

Definition 5.4.3. The *degeneracy* of a graph H is defined as the maximum, over all subgraphs $H' \subseteq H$, of the minimum degree of H' . H is said to be *d-degenerate* if its degeneracy is at most d .

Equivalently, H is *d-degenerate* if its vertices can be ordered as v_1, \dots, v_n with the property that, for all $i \in [n]$, v_i has at most d neighbors which precede it in the ordering, that is, at most d neighbors v_j with $j < i$.

From Lemma 5.2.2, we see that a *d-degenerate* graph has average degree at most $2d$. On the other hand, the H in Proposition 5.4.2 is an example of a graph with constant average degree and degeneracy $\sqrt{n} - 1$. Thus, we see that having bounded degeneracy is a strictly stronger condition than having bounded average degree. In particular, Proposition 5.4.1 implies that graphs with high degeneracy have large Ramsey numbers, as shown in the following result.

Theorem 5.4.4. *Let H be a graph of degeneracy d . Then $r(H) > 2^{\frac{d-1}{2}}$.*

Proof. By the definition of degeneracy, there is a subgraph $H' \subseteq H$ with minimum degree at least d , and thus also average degree at least d . Then Proposition 5.4.1 implies that

$$r(H) \geq r(H') > 2^{\frac{d-1}{2}}. \quad \square$$

Given this, we can now amend our naïve conjecture to the following fundamental conjecture of Burr and Erdős [8].

Conjecture 5.4.5 (Burr–Erdős [8]). *Graphs of bounded degeneracy have linear Ramsey numbers.*

More precisely, for every $d \geq 1$ there exists $C \geq 1$ such that the following holds. If an n -vertex graph H is d -degenerate, then $r(H) \leq Cn$.

The Burr–Erdős conjecture has a long history, with many important partial results. The first major breakthrough in this direction was a theorem of Chvátal, Rödl, Szemerédi, and Trotter [12], which established the Burr–Erdős conjecture under the stronger assumption that H has bounded maximum degree.

Theorem 5.4.6 (Chvátal–Rödl–Szemerédi–Trotter [12]). *Graphs of bounded maximum degree have linear Ramsey numbers.*

More precisely, for every $\Delta \geq 1$, there exists $C \geq 1$ such that the following holds. If an n -vertex graph H has maximum degree at most Δ , then $r(H) \leq Cn$.

This result was extremely important, and so was the proof technique they introduced; this theorem is the first result in Ramsey theory to be proved via the so-called *regularity method*, whose basis is the fundamental *regularity lemma* of Szemerédi [51]. This method has become one of the most important techniques in Ramsey theory and in extremal graph theory more broadly, and we will discuss it in more depth shortly. For now, let us only remark that this proof technique gives truly enormous bounds on how large C has to be as a function of Δ ; namely their proof showed that Theorem 5.4.6 is true for

$$C = 2^{\left\{ 2^{\dots^{2^2}} \right\}^{2^{100\Delta}}}.$$

This enormous bound is one of several reasons why many researchers attempted to find alternative proofs of Theorem 5.4.6.

5.4.1 Greedy embedding

There are now (at least) two other techniques known for proving Theorem 5.4.6, both of which are very important in their own right. The first is the *greedy embedding technique*, which was developed in this context by Graham, Rödl, and Ruciński [26, 27], although it goes back in some form at least to work of Erdős and Hajnal [22]. We will unfortunately not have time to discuss this technique in detail in this course, but let us see a high-level overview of how it works.

Proof sketch of Theorem 5.4.6 using greedy embedding. Let H be an n -vertex graph of maximum degree at most Δ , and let $N = Cn$ for a large constant $C = C(\Delta)$ that we choose appropriately. Fix a red/blue coloring of $E(K_N)$. Our goal is to attempt to find a red copy of H in a greedy manner; we'll then show that, if we fail, we will be able to find a blue copy of H .

Let us label the vertices of H as v_1, \dots, v_n . Define $V_1 = V_2 = \dots = V_n = V(K_N)$. We think of V_i as the set of candidate vertices for v_i , and will attempt to embed the vertices of H one at a time, at each step updating the set of candidate vertices. We fix some small parameter $\varepsilon > 0$.

Note that if we pick where to embed v_i into V_i , we need to update our candidate sets. Indeed, since our goal is to build a red copy of H , if we choose where to place v_i , we need to shrink each V_j , for all j such that $v_i v_j \in E(H)$, to only include the red neighbors of the chosen embedding of v_i . Let us call a vertex $w \in V_i$ *prolific* if it has the following property: if we choose to embed v_i as w , then each candidate set shrinks by at most a factor of ε . In other words, w is prolific if its red neighborhood in V_j has size at least $\varepsilon|V_j|$, for every j such that $v_i v_j \in E(H)$.

Our embedding rule is now as follows. If there is a prolific vertex in V_1 , we embed v_1 there and update all the candidate sets appropriately. If there is now a prolific vertex in V_2 , we embed v_2 there and update all the candidate sets. We continue in this way as long as we can.

If this process gets to the end, that is, if we embed v_n into V_n , then we have found a red copy of H . So we may assume that the process gets stuck at some step i . Note that every candidate set shrinks at most Δ times, since H has maximum degree at most Δ , and moreover every time it shrinks it does so by at most a factor of ε . Thus, when we get stuck, we still have that $|V_j| \geq \varepsilon^\Delta N$ for all j . In particular, $|V_i| \geq \varepsilon^\Delta N$. Moreover, since we got stuck, there is no prolific vertex in V_i . That is, for every vertex $w \in V_i$, there is some j such that the red neighborhood of w in V_j has size less than $\varepsilon|V_j|$. There are at most Δ options for this choice of j , so by the pigeonhole principle, there is some fixed $j \in [n]$ and some set $W_i \subseteq V_i$ with $|W_i| \geq \frac{1}{\Delta}|V_i|$ such that every $w \in W_i$ has a red neighborhood in V_j of size less than $\varepsilon|V_j|$.

We have thus proved the following lemma. If this greedy embedding procedure ever gets stuck, we find two sets W_i, V_j with $|W_i| \geq \frac{1}{\Delta}\varepsilon^\Delta N$ and $|V_j| \geq \varepsilon^\Delta N$, and with the property that the density of red edges between W_i and V_j is less than ε . In other words, we have found two sets A_1, A_2 with $|A_1|, |A_2| \geq \frac{1}{\Delta}\varepsilon^\Delta N$, and such that the density of *blue* edges between A_1 and A_2 is at least $1 - \varepsilon$.

We now iterate this lemma, as follows. Inside A_1 , we run the same procedure to attempt to greedily embed H in red. If we succeed, we are done. If we fail, we find two sets $A_{11}, A_{12} \subseteq A_1$ with blue density between them at least $1 - \varepsilon$, where $|A_{11}|, |A_{12}| \geq (\frac{1}{\Delta}\varepsilon^\Delta)^2 N$. We also run the same procedure inside A_2 to find two such sets A_{21}, A_{22} . Moreover, since the blue density between A_1 and A_2 was at least $1 - \varepsilon$, we can ensure³ that the blue density between A_{1i} and A_{2j} is at least $1 - \varepsilon$, for all $i, j \in [2]$.

In other words, we've now found *four* sets, each of size at least $(\frac{1}{\Delta}\varepsilon^\Delta)^2 N$, such that the blue density between every pair is at least $1 - \varepsilon$. Continuing in this manner k times, we can find 2^k such sets, each with size at least $(\frac{1}{\Delta}\varepsilon^\Delta)^k N$, and with all pairwise blue densities at least $1 - \varepsilon$. We now do this until $2^k \geq \Delta + 1$ (i.e. pick $k = \lceil \log(\Delta + 1) \rceil$), and we thus obtain at least $\Delta + 1$ sets, which we rename $B_1, \dots, B_{\Delta+1}$.

Since H has maximum degree at most Δ , it is $(\Delta + 1)$ -colorable, i.e. it can be partitioned into $\Delta + 1$ independent sets $C_1, \dots, C_{\Delta+1}$. Note that

$$|B_i| \geq \left(\frac{1}{\Delta}\varepsilon^\Delta\right)^k N \geq n,$$

where we can ensure the final inequality by picking C sufficiently large as a function of Δ and ε (and thus k , which is itself a function of Δ). Thus, each set B_i is large enough to accommodate embedding C_i . Moreover, one can check that if ε is sufficiently small (e.g. $\varepsilon = \Delta^{-2}$ suffices), then the greedy embedding strategy we tried for red is now *guaranteed* to work in blue. Namely, we greedily embed H in blue, ensuring that all vertices of C_i get embedded into B_i , and updating all candidate sets at every step. The strong density conditions we know about blue imply that we will never get stuck. \square

Examining the proof sketch above, we see that it gives a bound of the form $C \leq 2^{O(\Delta(\log \Delta)^2)}$. Moreover, in case H is bipartite, the iteration step is unnecessary, and we

³There is some subtlety in doing this step correctly; since A_{1i} and A_{2j} are rather small subsets of A_1, A_2 , one needs an extra argument to ensure that the blue density remains high when we restrict to them.

can simply take $k = 1$ in the proof above, and thus obtain a bound of $C \leq 2^{O(\Delta \log \Delta)}$. In other words, the greedy embedding technique allowed Graham, Rödl, and Ruciński to prove the following more refined version of Theorem 5.4.6.

Theorem 5.4.7 (Graham–Rödl–Ruciński [26, 27]). *There exists an absolute constant $M > 0$ such that the following holds. If H is an n -vertex graph with maximum degree at most Δ , then*

$$r(H) \leq 2^{M\Delta(\log \Delta)^2} n.$$

Moreover, if H is bipartite, we have the stronger bound

$$r(H) \leq 2^{M\Delta \log \Delta} n.$$

Remarkably, Graham, Rödl, and Ruciński also proved that their upper bound is nearly tight, even for bipartite graphs.

Theorem 5.4.8 (Graham–Rödl–Ruciński [27]). *There exists an absolute constant $c > 0$ such that the following holds. For every $n > \Delta > 1$, there is an n -vertex bipartite graph H with maximum degree Δ which satisfies*

$$r(H) \geq 2^{c\Delta} n.$$

We will not prove Theorem 5.4.8 in this course, but let us briefly remark on the technique. The bipartite graph H in the theorem is defined randomly; for example, one can pick it uniformly at random among all bipartite n -vertex Δ -regular graphs. One then wants to show that, with high probability over the random choice of H , it satisfies $r(H) \geq 2^{c\Delta} n$. To do this, one needs to exhibit a coloring on $N = 2^{c\Delta} n$ vertices with no monochromatic copy of H . This is done as follows. First, for an appropriate constant $a > c > 0$, one picks a uniformly random red/blue coloring χ of $E(K_A)$, where $A = 2^{a\Delta}$. One then “blows up” χ to a coloring of $E(K_N)$ as follows. We partition $V(K_N)$ into A parts V_1, \dots, V_A , each of size $N/A = 2^{(c-a)\Delta} n$. We then color all edges between parts V_i and V_j according to the color $\chi(v_i, v_j)$, where $v_i, v_j \in V(K_A)$. Finally, all edges within a part V_i are colored red. Note that since $a > c$, each part V_i has size $N/A = 2^{(c-a)\Delta} n$, which is much smaller than n (assuming a and c are chosen appropriately). Thus, any monochromatic copy of H must use vertices from many different parts V_i . However, since the coloring χ is random, one can show that with high probability, any large collection of parts—or equivalently, any large collection of vertices of K_A —includes many edges of both colors. Moreover, since H is random, one can show that its edges are extremely well-distributed. Because of this, one can show that any potential embedding of H into K_N cannot entirely avoid one of the two colors.

Looking back at the greedy embedding proof sketch above, one might be struck by the fact that the colors play such asymmetrical roles; we keep trying, insistently, to embed H in red, and only when we have failed many times do we relent and succeed in embedding it in blue. This asymmetry is in fact a weakness of the proof technique, and Conlon, Fox, and Sudakov [17] were able to improve the bound of Theorem 5.4.7 to $r(H) \leq 2^{O(\Delta \log \Delta)} n$ for every n -vertex graph H with maximum degree Δ , by modifying the greedy embedding

technique so that both colors play roughly the same role. Unfortunately, it is still not known if this technique can be used to remove the final logarithmic factor, and thus match the lower bound of Theorem 5.4.8.

Moreover, this discussion hints at another, more fundamental, weakness of the greedy embedding technique, which is that it is tailor-made for the two-color case. Indeed, the entire upshot of the technique is that *failing* to find H in red tells us something about the blue edges. In case there are three or more colors, it is not at all clear how to obtain useful information from the failure of the first embedding. As far as I am aware, no one has been able to use the greedy embedding technique to prove any results on $r(H; q)$ for any H and any $q \geq 3$.
